The global surface temperature changes of the climate system are generally analysed with the classical forcing-feedback framework as described in Box 7.1 (Equation 7.1). In this equation α is the net feedback parameter (W m^{-2} °C^{-1}). As surface temperature changes in response to the TOA energy imbalance, many other climate variables also change, thus affecting the radiative flux at the TOA. The aggregate feedback parameter can then be decomposed into an approximate sum of terms $\alpha = \sum_x \alpha_x$, where x is a vector representing variables that have a direct effect on the net TOA radiative flux N and $\alpha_x = \frac{\partial N}{\partial x}\frac{dx}{dT}$. Following

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the conventional definition, the physical climate feedbacks are here decomposed into terms associated with a vertically uniform temperature change (Planck response, P), changes in the water vapour plus temperature lapse rate (WV+LR), surface albedo (A) and clouds (C). The water vapour plus temperature lapse rate feedback is further decomposed using two different approaches, one based on changes in specific humidity, the other on changes in relative humidity. Biogeochemical feedbacks arise due to changes in aerosols and atmospheric chemical composition in response to changes in surface temperature, and Gregory et al. (2009) and Raes et al. (2010) show that they can be analysed using the same framework as for the physical climate feedbacks (see Chapter 5, Section 5.4 and Chapter 6, Section 6.4.5 Similarly, feedbacks associated with biogeophysical and ice sheet changes can also be incorporated.

In global climate models, the feedback parameters α_x in global warming conditions are often estimated as the mean differences in the radiative fluxes between atmosphere-only simulations in which the change in SST is prescribed (Cess et al., 1990), or as the regression slope of change in radiation flux against change in global-mean surface air temperature using atmosphere-ocean coupled simulations with abrupt CO_2 changes (*abrupt4xCO2*) for 150 years (Gregory et al., 2004; Andrews et al., 2012; Caldwell et al., 2016; see Box 7.1). Neither method is perfect, but both are useful and yield consistent results (Ringer et al., 2014). In the regression method, the radiative effects of land warming are excluded from the effective radiative forcing due to doubling of CO_2 (Section 7.3.2), which may overestimate feedback values by about 10%. At the same time, the feedback calculated using the regression over years 1–150 ignores its state-dependence on multi-centennial time scales (Section 7.4.3), probably giving an underestimate of α by about 10% (Rugenstein et al., 2019a). These effects are both small and cancel each other in the ensemble mean, justifying the use of regression over 150 years as an approximation to feedbacks in ESMs.

The change of the TOA radiative flux N as a function of the change of a climate variable x (such as water vapour) is commonly computed using the 'radiative kernel' method (Soden et al., 2008). In this method, the kernel $\partial N/\partial x$ is evaluated by perturbing x within a radiation code. Then multiplying the kernel by dx/dT inferred from observations, meteorological analysis or GCMs produces a value of α_x.

Feedback parameters from lines of evidence other than global models are estimated in various ways. For example, observational data combined with GCM simulations could produce an emergent constraint on a particular feedback (Hall and Qu, 2006; Klein and Hall, 2015), or the observed interannual fluctuations in the global-mean TOA radiation and the surface air temperature, to which the linear regression analysis is applied, could generate a direct estimate of the climate feedback assuming that the feedback associated with internal climate variability at short time scales can be a surrogate of the feedback to CO_2-induced warming (Dessler, 2013; Loeb et al., 2016). The assumption is not trivial, but can be justified given that the climate feedbacks are fast enough to occur at the interannual time scale. Indeed, a broad agreement has been obtained in estimates of individual physical climate feedbacks based on interannual variability and longer climate change timescales in GCMs (Zhou et al., 2015; Colman and Hanson, 2017). This means that the climate feedbacks estimated from the observed interannual fluctuations are representative of the longer-term feedbacks (decades to centuries). Care must be taken for these observational estimates because they can be sensitive to details of the calculation such as data sets and periods used (Dessler, 2013; Proistosescu et al., 2018). In particular, there would be a dependence of physical feedbacks on the surface warming pattern at the interannual time scale due, for example, to El Niño-Southern Oscillation. However, this effect both amplifies and suppresses the feedback when data include the positive and negative phases of the interannual fluctuation, and therefore the net bias will be small.

In summary, the classical forcing-feedback framework has been extended to include biogeophysical and non-CO_2-biogeochemical feedbacks in addition to the physical feedbacks. It has also been used to analyse seasonal and interannual to decadal climate variations in observations and ESMs, in addition to long-term climate changes as seen in *abrupt4xCO2* experiments. These developments allow an assessment of the feedbacks based on a larger variety of lines of evidence compared to AR5.

7.4.2 Assessing climate feedbacks

ACCEPTED VERSION SUBJECT TO FINAL EDITING

This section provides an overall assessment of individual feedback parameters, α_x, by combining different lines of evidence from observations, theory, process models and ESMs. To achieve this, we review the understanding of the key processes governing the feedbacks, why the feedback estimates differ among models, studies or approaches, and the extent to which these approaches yield consistent results. The individual terms assessed are the Planck response (Section 7.4.2.1) and feedbacks associated with changes in water vapour and lapse rate (Section 7.4.2.2), surface albedo (Section 7.4.2.3), clouds (Section 7.4.2.4), biogeophysical and non-CO_2 biogeochemical processes (Section 7.4.2.5), and ice sheets (Section 7.4.2.6). A synthesis is provided in Section 7.4.2.7. Climate feedbacks in CMIP6 models are then evaluated in Section 7.4.2.8, with an explanation of how they have been incorporated into the assessment.

7.4.2.1 Planck response

The Planck response represents the additional thermal or longwave (LW) emission to space arising from vertically uniform warming of the surface and the atmosphere. The Planck response α_P, often called the Planck feedback, plays a fundamental stabilizing role in Earth's climate and has a value that is strongly negative: a warmer planet radiates more energy to space. A crude estimate of α_P can be made using the normalized greenhouse effect $\tilde{g}$, defined as the ratio between the greenhouse effect G and the upwelling LW flux at the surface (Raval and Ramanathan, 1989). Current estimates (Section 7.2, Figure 7.2) give G = 159 W m^{-2} and $\tilde{g} \approx 0.4$. Assuming $\tilde{g}$ is constant, one obtains for a surface temperature T_s = 288K, $\alpha_P = (\tilde{g} - 1)\, 4\, \sigma\, T_s^3 \approx -3.3$ W m^{-2} °C^{-1}, where σ is the Stefan-Boltzmann constant. This parameter α_P is estimated more accurately using kernels obtained from meteorological reanalysis or climate simulations (Soden and Held, 2006; Dessler, 2013; Vial et al., 2013; Caldwell et al., 2016; Colman and Hanson, 2017; Zelinka et al., 2020). Discrepancies among estimates primarily arise because differences in cloud distributions make the radiative kernels differ (Kramer et al., 2019). Using six different kernels, Zelinka et al. (2020) obtained a spread of ±0.1 W m^{-2} °C^{-1} (one standard deviation). Discrepancies among estimates secondarily arise from differences in the pattern of equilibrium surface temperature changes among ESMs. For the CMIP5 and CMIP6 models this introduces a spread of ±0.04 W m^{-2} °C^{-1} (one standard deviation). The multi-kernel and multi-model mean of α_P is equal to –3.20 W m^{-2} °C^{-1} for the CMIP5 and –3.22 W m^{-2} °C^{-1} for the CMIP6 models (Supplementary Table 7.SM.5). Overall, there is *high confidence* in the estimate of the Planck response, which is assessed to be α_P = –3.22 W m^{-2} °C^{-1} with a *very likely* range of –3.4 to –3.0 W m^{-2} °C^{-1} and a *likely range* of –3.3 to –3.1 W m^{-2} °C^{-1}.

The Planck temperature response ΔT_P is the equilibrium temperature change in response to a forcing ΔF when the net feedback parameter is equal to the Planck response parameter: $\Delta T_P = -\Delta F / \alpha_P$.

7.4.2.2 Water vapour and temperature lapse rate feedbacks

Two decompositions are generally used to analyse the feedbacks associated with a change in the water vapour and temperature lapse rate in the troposphere. As in any system, many feedback decompositions are possible, each of them highlighting a particular property or aspect of the system (Ingram, 2010; Held and Shell, 2012; Dufresne and Saint-Lu, 2016). The first decomposition considers separately the changes (and therefore feedbacks) in the lapse rate (LR) and specific humidity (WV). The second decomposition considers changes in the lapse rate assuming constant relative humidity (LR*) separately from changes in relative humidity (RH).

The specific humidity (WV) feedback, also known as the water vapour feedback, quantifies the change in radiative flux at the TOA due to changes in atmospheric water vapour concentration associated with a change in global mean air surface temperature. According to theory, observations and models, the water vapour increase approximately follows the Clausius-Clapeyron relationship at the global scale with regional differences dominated by dynamical processes (Chapter 8, Section 8.2.1; Sherwood et al., 2010b; Chung et al., 2014; Romps, 2014; Liu et al., 2018; Schröder et al., 2019). Greater atmospheric water vapour content, particularly in the upper troposphere, results in enhanced absorption of LW and SW radiation and reduced outgoing radiation. This is a positive feedback. Atmospheric moistening has been detected in satellite records

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Chapter 2, Section 2.3.1.3.3), is simulated by climate models (Chapter 3, Section 3.3.2.1), and the estimates agree within model and observational uncertainty (Soden et al., 2005; Dessler, 2013; Gordon et al., 2013; Chung et al., 2014). The estimate of this feedback inferred from satellite observations is $\alpha_{WV} = 1.85 \pm 0.32$ W m^{-2} °C^{-1} (Liu et al., 2018). This is consistent with the value $\alpha_{WV} = 1.77 \pm 0.20$ W m^{-2} °C^{-1} (one standard deviation) obtained with CMIP5 and CMIP6 models (Zelinka et al., 2020).

The lapse rate (LR) feedback quantifies the change in radiative flux at the TOA due to a non-uniform change in the vertical temperature profile. In the tropics, the vertical temperature profile is mainly driven by moist convection and is close to a moist adiabat. The warming is larger in the upper troposphere than in the lower troposphere (Manabe and Wetherald, 1975; Santer et al., 2005; Bony et al., 2006), leading to a larger radiative emission to space and therefore a negative feedback. This larger warming in the upper troposphere than at the surface has been observed over the last twenty years thanks to the availability of sufficiently accurate observations (Chapter 2, Section 2.3.1.2.2). In the extra-tropics, the vertical temperature profile is mainly driven by a balance between radiation, meridional heat transport and ocean heat uptake (Rose et al., 2014). Strong wintertime temperature inversions lead to warming that is larger in the lower troposphere (Payne et al., 2015; Feldl et al., 2017a) and a positive lapse rate feedback in polar regions (Manabe and Wetherald, 1975; Bintanja et al., 2012; Pithan and Mauritsen, 2014; Section 7.4.4.1). However, the tropical contribution dominates, leading to a negative global mean lapse rate feedback (Soden and Held, 2006; Dessler, 2013; Vial et al., 2013; Caldwell et al., 2016). The LR feedback has been estimated at interannual time scales using meteorological reanalysis and satellite measurements of TOA fluxes (Dessler, 2013). These estimates from climate variability are consistent between observations and ESMs (Dessler, 2013; Colman and Hanson, 2017). The mean and standard deviation of this feedback under global warming based on the cited studies are $\alpha_{LR} = -0.50 \pm 0.20$ W m^{-2} °C^{-1} (Dessler, 2013; Caldwell et al., 2016; Colman and Hanson, 2017; Zelinka et al., 2020).

The second decomposition was proposed by Held and Shell (2012) to separate the response that would occur under the assumption that relative humidity remains constant from that due to the change in relative humidity. The feedback is decomposed into three: (1) change in water vapour due to an identical temperature increase at the surface and throughout the troposphere assuming constant relative humidity, which will be called the Clausius-Clapeyron (CC) feedback here; (2) change in lapse rate assuming constant relative humidity (LR*); (3) change in relative humidity (RH). Since AR5 it has been clarified that by construction, the sum of the temperature lapse rate and specific humidity (LR+WV) feedbacks is equal to the sum of the Clausius-Clapeyron, lapse rate assuming constant relative humidity, and changes in relative humidity (CC+LR*+RH) feedbacks. Therefore, each of these two sums may simply be referred to as the "water vapour plus lapse rate" feedback.

The CC feedback has a large positive value due to well understood thermodynamic and radiative processes: $\alpha_{CC} = 1.36 \pm 0.04$ W m^{-2} °C^{-1} (one standard deviation) (Held and Shell, 2012; Zelinka et al., 2020). The lapse rate feedback assuming a constant relative humidity LR* in CMIP6 models has small absolute values ($\alpha_{LR*} = -0.10 \pm 0.07$ W m^{-2} °C^{-1} (one standard deviation)), as expected from theoretical arguments (Ingram, 2010, 2013). It includes the pattern effect of surface warming that modulates the lapse rate and associated specific humidity changes (Po-Chedley et al., 2018a). The relative humidity feedback is close to zero ($\alpha_{RH} = 0.00 \pm 0.06$ W m^{-2} °C^{-1} (one standard deviation)) and the spread among models is confined to the tropics (Sherwood et al., 2010a; Vial et al., 2013; Takahashi et al., 2016; Po-Chedley et al., 2018a). The change in upper tropospheric RH is closely related to model representation of current climate (Sherwood et al., 2010a; Po-Chedley et al., 2019), and a reduction in model RH biases is expected to reduce the uncertainty of the RH feedback. At inter-annual time scales, it has been shown that the change in RH in the tropics is related to the change of the spatial organisation of deep convection (Holloway et al., 2017; Bony et al., 2020).

Both decompositions allow estimates of the sum of the lapse rate and specific humidity feedbacks α_{LR+WV}. The multi-kernel and multi-model mean of α_{LR+WV} is equal to 1.24 and 1.26 W m^{-2} °C^{-1} respectively for CMIP5 and CMIP6 models, with a standard deviation of 0.10 W m^{-2} °C^{-1} (Zelinka et al., 2020). These values are larger than the recently assessed value of 1.15 W m^{-2} °C^{-1} by Sherwood et al. (2020) as a larger set of kernels, including those obtained from meteorological reanalysis, are used here.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Since AR5, the effect of the water vapour increase in the stratosphere with global warming has been investigated by different studies. This increase produces a positive feedback between 0.1 and 0.3 W m^{-2} °C^{-1} if the stratospheric radiative response is computed assuming temperatures that are adjusted with fixed dynamical heating (Dessler et al., 2013; Banerjee et al., 2019). However, various feedbacks reduce this temperature adjustment and the overall physical (water vapour, temperature and dynamical) stratospheric feedback becomes much smaller (0.0 to 0.1 W m^{-2} °C^{-1}) (Huang et al., 2016, 2020; Li and Newman, 2020), with uncertainty arising from limitations of current ESMs in simulating stratospheric processes. The total stratospheric feedback is assessed at 0.05 ± 0.1 W m^{-2} °C^{-1} (one standard deviation).

The combined water vapour plus lapse rate feedback is positive. The main physical processes that drive this feedback are well understood and supported by multiple lines of evidence including models, theory and observations. The combined water vapour plus lapse rate feedback parameter is assessed to be α_{LR+WV} = 1.30 W m^{-2} °C^{-1}, with a *very likely* range of 1.1 to 1.5 W m^{-2} °C^{-1} and a *likely* range of 1.2 to 1.4 W m^{-2} °C^{-1} with *high confidence.*

7.4.2.3 Surface albedo feedback

Surface albedo is determined primarily by reflectance at Earth's surface, but also by the spectral and angular distribution of incident solar radiation. Changes in surface albedo result in changes in planetary albedo that are roughly reduced by two-thirds, owing to atmospheric absorption and scattering, with variability and uncertainty arising primarily from clouds (Bender, 2011; Donohoe and Battisti, 2011; Block and Mauritsen, 2013). Temperature change induces surface albedo change through several direct and indirect means. In the present climate and at multidecadal time scales, the largest contributions by far are changes in the extent of sea ice and seasonal snow cover, as these media are highly reflective and are located in regions that are close to the melting temperature (Chapter 2, Sections 2.3.2.1 and 2.3.2.2). Reduced snow cover on sea ice may contribute as much to albedo feedback as reduced extent of sea ice (Zhang et al., 2019). Changes in the snow metamorphic rate, which generally reduces snow albedo with warmer temperature, and warming-induced consolidation of light absorbing impurities near the surface, also contribute secondarily to the albedo feedback (Flanner and Zender, 2006; Qu and Hall, 2007; Doherty et al., 2013; Tuzet et al., 2017). Other contributors to albedo change include vegetation state (assessed separately in Section 7.4.2.5), soil wetness, and ocean roughness.

Several studies have attempted to derive surface albedo feedback from observations of multidecadal changes in climate, but only over limited spatial and inconsistent temporal domains, inhibiting a purely observational synthesis of global α_A. Flanner et al. (2011) applied satellite observations to determine that the northern hemisphere (NH) cryosphere contribution to global α_A over 1979–2008 was 0.48 [*likely* range 0.29 to 0.78] W m^{-2} °C^{-1}, with roughly equal contributions from changes in land snow cover and sea ice. Since AR5, and over similar periods of observation, Crook and Forster (2014) found an estimate of 0.8 ± 0.3 W m^{-2} °C^{-1} (one standard deviation) for the total NH extratropical surface albedo feedback, when averaged over global surface area. For the Arctic sea ice alone, Pistone et al. (2014) and Cao et al. (2015) estimated the contribution to global α_A to be 0.31 ± 0.04 W m^{-2} °C^{-1} (one standard deviation) and 0.31 ± 0.08 W m^{-2} °C^{-1} (one standard deviation), respectively, whereas Donohoe et al. (2020) estimated it to be only 0.16 ± 0.04 W m^{-2} °C^{-1} (one standard deviation). Much of this discrepancy can be traced to different techniques and data used for assessing the attenuation of surface albedo change by Arctic clouds. For the NH land snow, Chen et al. (2016) estimated that observed changes during 1982–2013 contributed (after converting from NH temperature change to global mean temperature change) by 0.1 W m^{-2} °C^{-1} to global α_A, smaller than the estimate of 0.24 W m^{-2} °C^{-1} from Flanner et al. (2011). The contribution of the southern hemisphere (SH) to global α_A is expected to be small because seasonal snow cover extent in the SH is limited, and trends in SH sea ice extent are relatively flat over much of the satellite record (Chapter 2, Section 2.3.2).

CMIP5 and CMIP6 models show moderate spread in global α_A determined from century timescale changes (Qu and Hall, 2014; Schneider et al., 2018; Thackeray and Hall, 2019; Zelinka et al., 2020), owing to variations in modelled sea-ice loss and snow cover response in boreal forest regions. The multi-model mean global-scale α_A (from all contributions) over the 21st century in CMIP5 models under the RCP8.5 scenario

ACCEPTED VERSION SUBJECT TO FINAL EDITING

was derived by Schneider et al. (2018) to be 0.40 ± 0.10 W m^{-2} °C^{-1} (one standard deviation). Moreover, they found that modelled α_A does not decline over the 21st century, despite large losses of snow and sea ice, though a weakened feedback is apparent after 2100. Using the idealized *abrupt4xCO2* as for the other feedbacks, the estimate of the global-scale albedo feedback in the CMIP5 models is 0.35± 0.08 W m^{-2}°C^{-1} (one standard deviation) (Vial et al., 2013; Caldwell et al., 2016). The CMIP6 multi-model mean varies from 0.3 to 0.5 W m^{-2}°C^{-1} depending on the kernel used (Zelinka et al., 2020). Donohoe et al. (2020) derived a multi-model mean α_A and its inter-model spread of 0.37 ± 0.19 W m^{-2} °C^{-1} from the CMIP5 *abrupt4xCO2* ensemble, employing model-specific estimates of atmospheric attenuation and thereby avoiding bias associated with use of a single radiative kernel.

The surface albedo feedback estimates using centennial changes have been shown to be highly correlated to those using seasonal regional changes for NH land snow (Qu and Hall, 2014) and Arctic sea ice (Thackeray and Hall, 2019). For the NH land snow, the physics underpinning this relationship being credible, this opens the possibility to use it as an emergent constraint (Qu and Hall, 2014). Considering only the 8 models whose seasonal cycle of albedo feedback falls within the observational range does not change the multi-model mean contribution to global α_A (0.08 W m^{-2}°C^{-1}) but decreases the inter-model spread by a factor of two (from ± 0.03 to ± 0.015 W m^{-2}°C^{-1}) (Qu and Hall, 2014). For the Arctic sea-ice, Thackeray and Hall (2019) show that the seasonal cycle also provides an emergent constraint, at least until mid-century when the relationship degrades. They find that the CMIP5 multi-model mean of the Arctic sea-ice contribution to α_A is 0.13 W m^{-2} °C^{-1} and that the inter-model spread is reduced by a factor of two (from ± 0.04 to ± 0.02 W m^{-2} °C^{-1}) when the emergent constraint is used. This model estimate is smaller than observational estimates (Pistone et al., 2014; Cao et al., 2015) except those of Donohoe et al. (2020). This can be traced to CMIP5 models generally underestimating the rate of Arctic sea ice loss during recent decades (Stroeve et al., 2012; Flato et al., 2013; Chapter 9, Section 9.3.1), though this may also be an expression of internal variability, since the observed behaviour is captured within large ensemble simulations (Notz, 2015). CMIP6 models better capture the observed Arctic sea ice decline (Chapter 3, Section 3.4.1). In the SH the opposite situation is observed. Observations show relatively flat trends in SH sea ice over the satellite era (Chapter 2, Section 2.3.2.1) whereas CMIP5 models simulate a small decrease (Chapter 3, Section 3.4.1). SH α_A is presumably larger in models than observations but only contribute to about one quarter of the global α_A. Thus, we assess that α_A estimates are consistent, at global scale, in CMIP5 and CMIP6 models and satellite observations, though hemispheric differences and the role of internal variability need to be further explored.

Based on the multiple lines of evidence presented above that include observations, CMIP5 and CMIP6 models and theory, the global surface albedo feedback is assessed to be positive with *high confidence*. The basic phenomena that drive this feedback are well understood and the different studies cover a large variety of hypotheses or behaviours, including how the evolution of clouds affects this feedback. The value of the global surface albedo feedback is assessed to be α_A = 0.35 W m^{-2} °C^{-1}, with a *very likely* range from 0.10 to 0.60 W m^{-2} °C^{-1} and a *likely* range from 0.25 to 0.45 W m^{-2} °C^{-1} with *high confidence*.

7.4.2.4 Cloud feedbacks

7.4.2.4.1 Decomposition of clouds into regimes

Clouds can be formed almost anywhere in the atmosphere when moist air parcels rise and cool, enabling the water vapour to condense. The cloud droplets, ice crystals frozen from small water droplets, and their mixture may further grow into large particles of rain, snow, or drizzle. These microphysical processes interact with aerosols, radiation and atmospheric circulation, resulting in a highly complex set of processes governing cloud formation and lifecycles that operate across a wide range of spatial and temporal scales.

Clouds have various types, from optically thick convective clouds to thin stratus and cirrus clouds, depending upon thermodynamic conditions and large-scale circulation (Figure 7.9). Over the equatorial warm pool and inter-tropical convergence zone (ITCZ) regions, high SSTs stimulate the development of deep convective cloud systems, which are accompanied by anvil and cirrus clouds near the tropopause where the convective air outflows. The large-scale circulation associated with these convective clouds leads to subsidence over the subtropical cool ocean, where deep convection is suppressed by a lower tropospheric

ACCEPTED VERSION SUBJECT TO FINAL EDITING

inversion layer maintained by the subsidence and promoting the formation of shallow cumulus and stratocumulus clouds. In the extratropics, mid-latitude storm tracks control cloud formation, which occurs primarily in the frontal bands of extratropical cyclones. Since liquid droplets do not freeze spontaneously at temperatures warmer than approximately –40°C and ice nucleating particles that can aid freezing at warmer temperatures are scarce (see Section 7.3.3), extratropical clouds often consist both of super-cooled liquid and ice crystals, resulting in mixed-phase clouds.

In the global energy budget at TOA, clouds affect SW radiation by reflecting sunlight due to their high albedo (cooling the climate system) and also LW radiation by absorbing the energy from the surface and emitting at a lower temperature to space, i.e., contributing to the greenhouse effect, warming the climate system. In general, the greenhouse effect of clouds strengthens with height whereas the SW reflection depends on the cloud optical properties. The effects of clouds on Earth's energy budget are measured by the cloud radiative effect (CRE), which is the difference in the TOA radiation between clear and all skies (see Section 7.2.1). In the present climate, the SW CRE tends to be compensated by the LW CRE over the equatorial warm pool, leading to the net CRE pattern showing large negative values over the eastern part of the subtropical ocean and the extratropical ocean due to the dominant influence of highly reflective marine low clouds.

In a first attempt to systematically evaluate ECS based on fully coupled GCMs in AR4, diverging cloud feedbacks were recognized as a dominant source of uncertainty. An advance in understanding the cloud feedback was to assess feedbacks separately for different cloud regimes (Gettelman and Sherwood, 2016). A thorough assessment of cloud feedbacks in different cloud regimes was carried out in AR5 (Boucher et al., 2013), which assigned *high* or *medium confidence* for some cloud feedbacks but *low* or *no confidence* for others (Table 7.9). Many studies that estimate the net cloud feedback using CMIP5 simulations (Vial et al., 2013; Caldwell et al., 2016; Zelinka et al., 2016; Colman and Hanson, 2017) show different values depending on the methodology and the set of models used, but often report a large inter-model spread of the feedback, with the 90% confidence interval spanning both weak negative and strong positive net feedbacks. Part of this diversity arises from the dependence of the model cloud feedbacks on the parameterization of clouds and their coupling to other sub-grid scale processes (Zhao et al., 2015).

Since AR5, community efforts have been undertaken to understand and quantify the cloud feedbacks in various cloud regimes coupled with large-scale atmospheric circulation (Bony et al., 2015). For some cloud regimes, alternative tools to ESMs, such as observations, theory, high-resolution cloud resolving models (CRMs), and Large Eddy Simulations (LES), help quantify the feedbacks. Consequently, the net cloud feedback derived from ESMs has been revised by assessing the regional cloud feedbacks separately and summing them with weighting by the ratio of fractional coverage of those clouds over the globe to give the global feedback, following an approach adopted in Sherwood et al. (2020). This "bottom-up" assessment is explained below with a summary of updated confidence of individual cloud feedback components (Table 7.9). Dependence of cloud feedbacks on evolving patterns of surface warming will be discussed in Section 7.4.4 and is not explicitly taken into account in the assessment presented in this section.

[START FIGURE 7.9 HERE]

Figure 7.9: Schematic cross section of diverse cloud responses to surface warming from the tropics to polar regions. Thick solid and dashed curves indicate the tropopause and the subtropical inversion layer in the current climate, respectively. Thin grey text and arrows represent robust responses in the thermodynamic structure to greenhouse warming, of relevance to cloud changes. Text and arrows in red, orange and green show the major cloud responses assessed with *high*, *medium* and *low confidence*, respectively, and the sign of their feedbacks to the surface warming is indicated in the parenthesis. Major advances since AR5 are listed in a box.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

7.4.2.4.2 Assessment for individual cloud regimes

High-cloud altitude feedback.

It has long been argued that cloud top altitude rises under global warming, concurrent with the rising of the tropopause at all latitudes (Marvel et al., 2015; Thompson et al., 2017). This increasing altitude of high clouds was identified in early generation GCMs and the tropical high-cloud altitude feedback was assessed to be positive with *high confidence* in AR5 (Boucher et al., 2013). This assessment is supported by a theoretical argument called the fixed anvil temperature mechanism, which ensures that the temperature of the convective detrainment layer does not change when the altitude of high-cloud tops increases with the rising tropopause (Hartmann and Larson, 2002). Because the cloud top temperature does not change significantly with global warming, cloud longwave emission does not increase even though the surface warms, resulting in an enhancement of the high-cloud greenhouse effect (a positive feedback; Yoshimori et al. (2020)). The upward shift of high clouds with surface warming is detected in observed interannual variability and trends in satellite records for recent decades (Chepfer et al., 2014; Norris et al., 2016; Saint-Lu et al., 2020). The observational detection is not always successful (Davies et al., 2017), but the cloud altitude shifts similarly in many CRM experiments (Khairoutdinov and Emanuel, 2013; Tsushima et al., 2014; Narenpitak et al., 2017). The high-cloud altitude feedback was estimated to be 0.5 W m^{-2}°C^{-1} based on GCMs in AR5, but is revised, using a recent re-evaluation that excludes aliasing effects by reduced low-cloud amounts, downward to 0.22 ± 0.12 W m^{-2} °C^{-1} (one standard deviation) (Zhou et al., 2014; Zelinka et al., 2020). In conclusion, there is *high confidence* in the positive high-cloud altitude feedback simulated in ESMs as it is supported by theoretical, observational, and process modelling studies.

Tropical high-cloud amount feedback.

Updrafts in convective plumes lead to detrainment of moisture at a level where the buoyancy diminishes, and thus deep convective clouds over high SSTs in the tropics are accompanied by anvil and cirrus clouds in the upper troposphere. These clouds, rather than the convective plumes themselves, play a substantial role in the global TOA radiation budget. In the present climate, the net CRE of these clouds is small due to a cancellation between the SW and LW components (Hartmann et al., 2001). However, high clouds with different optical properties could respond to surface warming differently, potentially perturbing this radiative balance and therefore leading to a non-zero feedback.

A thermodynamic mechanism referred to as the 'stability iris effect' has been proposed to explain that the anvil cloud amount decreases with surface warming (Bony et al., 2016). In this mechanism, a temperature-mediated increase of static stability in the upper troposphere, where convective detrainment occurs, acts to balance a weakened mass outflow from convective clouds, and thereby reduce anvil cloud areal coverage (Figure 7.9). The reduction of anvil cloud amount is accompanied by enhanced convective aggregation that causes a drying of the surrounding air and thereby increases the LW emission to space that acts as a negative feedback (Bony et al., 2020). This phenomenon is found in many CRM simulations (Emanuel et al., 2014; Wing and Emanuel, 2014; Wing et al., 2020) and also identified in observed interannual variability (Stein et al., 2017; Saint-Lu et al., 2020).

Despite the reduction of anvil cloud amount supported by several lines of evidence, estimates of radiative feedback due to high-cloud amount changes is highly uncertain in models. The assessment presented here is guided by combined analyses of TOA radiation and cloud fluctuations at interannual time scale using multiple satellite data sets. The observationally based local amount feedback associated with optically thick high clouds is negative, leading to its global contribution (by multiplying the mean tropical anvil cloud fraction of about 8%) of –0.24 ± 0.05 W m^{-2} °C^{-1} (one standard deviation) for LW (Vaillant de Guélis et al., 2018). Also, there is a positive feedback due to increase of optically thin cirrus clouds in the tropopause layer, estimated to be 0.09 ± 0.09 W m^{-2} °C^{-1} (one standard deviation) (Zhou et al., 2014). The negative LW feedback due to reduced amount of thick high clouds is partly compensated by the positive SW feedback (due to less reflection of solar radiation), so that the tropical high-cloud amount feedback is assessed to be equal to or smaller than their sum. Consistently, the net high cloud feedback in the tropical convective regime, including a part of the altitude feedback, is estimated to have the global contribution of –0.13 ± 0.06 W m^{-2} °C^{-1} (one standard deviation) (Williams and Pierrehumbert, 2017). The negative cloud LW feedback is considerably biased in CMIP5 GCMs (Mauritsen and Stevens, 2015; Su et al., 2017; Li et al., 2019) and highly uncertain primarily due to differences in the convective parameterization (Webb et al., 2015).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Furthermore, high-resolution CRM simulations cannot alone be used to constrain uncertainty because the results depend on parametrized cloud microphysics and turbulence (Bretherton et al., 2014; Ohno et al., 2019). Therefore, the tropical high-cloud amount feedback is assessed as negative but with *low confidence* given the lack of modelling evidence. Taking observational estimates altogether and methodological uncertainty into account, the global contribution of the high-cloud amount feedback is assessed to –0.15 ± 0.2 W m^{-2} °C^{-1} (one standard deviation).

Subtropical marine low-cloud feedback.

It has long been argued that the response of marine boundary layer clouds over the subtropical ocean to surface warming was the largest contributor to the spread among GCMs in the net cloud feedback (Boucher et al., 2013). However, uncertainty of the marine low-cloud feedback has been reduced considerably since AR5 through combined knowledge from theoretical, modelling, and observational studies (Klein et al., 2017). Processes that control the low clouds are complex and involve coupling with atmospheric motions on multiple scales, from the boundary layer turbulence to the large-scale subsidence, which may be represented by a combination of shallow and deep convective mixing (Sherwood et al., 2014).

In order to disentangle the large-scale processes that cause the cloud amount either to increase or decrease in response to the surface warming, the cloud feedback has been expressed in terms of several 'cloud controlling factors' (Qu et al., 2014, 2015; Zhai et al., 2015; Brient and Schneider, 2016; Myers and Norris, 2016; McCoy et al., 2017b). The advantage of this approach over conventional calculation of cloud feedbacks is that the temperature-mediated cloud response can be estimated without using information of the simulated cloud responses that are less well-constrained than the changes in the environmental conditions. Two dominant factors are identified for the subtropical low clouds: a thermodynamic effect due to rising SST that acts to reduce low cloud by enhancing cloud-top entrainment of dry air, and a stability effect accompanied by an enhanced inversion strength that acts to increase low cloud (Qu et al., 2014, 2015; Kawai et al., 2017). These controlling factors compensate with a varying degree in different ESMs, but can be constrained by referring to the observed seasonal or interannual relationship between the low-cloud amount and the controlling factors in the environment as a surrogate. The analysis leads to a positive local feedback that has the global contribution of 0.14–0.36 W m^{-2} °C^{-1} (Klein et al., 2017), to which the feedback in the stratocumulus regime dominates over the feedback in the trade cumulus regime (Cesana et al., 2019; Radtke et al., 2020). The stratocumulus feedback may be underestimated because explicit simulations using LES show a larger local feedback of up to 2.5 W m^{-2} °C^{-1}, corresponding to the global contribution of 0.2 W m^{-2} °C^{-1} by multiplying the mean tropical stratocumulus fraction of about 8% (Bretherton, 2015). Supported by different lines of evidence, the subtropical marine low-cloud feedback is assessed as positive with *high confidence*. Based on the combined estimate using LESs and the cloud controlling factor analysis, the global contribution of the feedback due to marine low clouds equatorward of 30° is assessed to be 0.2 ± 0.16 W m^{-2} °C^{-1} (one standard deviation), for which the range reflects methodological uncertainties.

Land cloud feedback.

Intensification of the global hydrological cycle is a robust feature of global warming, but at the same time, many land areas in the subtropics will experience drying at the surface and in the atmosphere (Chapter 8, Section 8.2.2). This occurs due to a limited water availability in these regions, where the cloudiness is consequently expected to decrease. Reduction in clouds over land are consistently identified in the CMIP5 models and also in a GCM with explicit convection (Bretherton et al., 2014; Kamae et al., 2016). Because low clouds make up the majority of subtropical land clouds, this reduced amount of low clouds reflects less solar radiation and leads to a positive feedback similar to the marine low clouds. The mean estimate of the global land cloud feedback in CMIP5 models is smaller than the marine low cloud feedback, 0.08 ± 0.08 W m^{-2} °C^{-1} (Zelinka et al., 2016). These values are nearly unchanged in CMIP6 (Zelinka et al., 2020). However, ESMs still have considerable biases in the climatological temperature and cloud fraction over land and the magnitude of this feedback has not yet been supported by observational evidence. Therefore, the feedback due to decreasing land clouds is assessed to be 0.08 ± 0.08 W m^{-2} °C^{-1} (one standard deviation) with *low confidence*.

Mid-latitude cloud amount feedback.

Poleward shifts in the mid-latitude jets are evident since the 1980s (Chapter 2, Section 2.3.1.4.3) and are a

ACCEPTED VERSION SUBJECT TO FINAL EDITING

feature of the large-scale circulation change in future projections (Chapter 4, Section 4.5.1.6). Because mid-latitude clouds over the North Pacific, North Atlantic, and Southern Ocean are induced mainly by extratropical cyclones in the storm tracks along the jets, it has been suggested that the jet shifts should be accompanied by poleward shifts in the mid-latitude clouds, which would result in a positive feedback through the reduced reflection of insolation (Boucher et al., 2013). However, studies since AR5 have revealed that this proposed mechanism does not apply in practice (Ceppi and Hartmann, 2015). While a poleward shift of mid-latitude cloud maxima in the free troposphere has been identified in satellite and ground-based observations (Bender et al., 2012; Eastman and Warren, 2013), associated changes in net CRE are small because the responses in high and low clouds to the jet shift act to cancel each other (Grise and Medeiros, 2016; Tselioudis et al., 2016; Zelinka et al., 2018). This cancellation is not well captured in ESMs (Lipat et al., 2017), but the above findings show that the mid-latitude cloud feedback is not dynamically driven by the poleward jet shifts, which are rather suggested to occur partly in response to high cloud changes (Li et al., 2018b).

Thermodynamics play an important role in controlling extratropical cloud amount equatorward of about 50° latitude. Recent studies showed using observed cloud controlling factors that the mid-latitude low cloud fractions decrease with rising SST, which also acts to weaken stability of the atmosphere unlike the subtropics (McCoy et al., 2017b). ESMs consistently show a decrease of cloud amounts and a resultant positive shortwave feedback in the 30°–40° latitude bands, which can be constrained using observations of seasonal migration of cloud amount (Zhai et al., 2015). Based on the qualitative agreement between observations and ESMs, the mid-latitude cloud amount feedback is assessed as positive with *medium confidence.* Following these emergent constraint studies using observations and CMIP5/6 models, the global contribution of net cloud amount feedback over 30°–60° ocean areas, covering 27% of the globe, is assigned 0.09 ± 0.1 W m^{-2} °C^{-1} (one standard deviation), in which the uncertainty reflects potential errors in models' low cloud response to changes in thermodynamic conditions.

Extratropical cloud optical depth feedback.

Mixed-phase clouds that consist of both liquid and ice are dominant over the Southern Ocean (50°–80°S), which accounts for 20% of the net CRE in the present climate (Matus and L'Ecuyer, 2017). It has been argued that the cloud optical depth (opacity) will increase over the Southern Ocean as warming drives the replacement of ice-dominated clouds with liquid-dominated clouds (Tan et al., 2019). Liquid clouds generally consist of many small cloud droplets, while the crystals in ice clouds are orders of magnitudes fewer in number and much larger, causing the liquid clouds to be optically thicker and thereby resulting in a negative feedback (Boucher et al., 2013). However, this phase change feedback works effectively only below freezing temperature (Lohmann and Neubauer, 2018; Terai et al., 2019) and other processes that increase or decrease liquid water path (LWP) may also affect the optical depth feedback (McCoy et al., 2019).

Due to insufficient amounts of super-cooled liquid water in the simulated atmospheric mean state, many CMIP5 models overestimated the conversion from ice to liquid clouds with climate warming and the resultant negative phase change feedback (Kay et al., 2016a; Tan et al., 2016; Lohmann and Neubauer, 2018). This feedback can be constrained using satellite-derived LWP observations over the past 20 years that enable estimates of both long-term trends and the interannual relationship with SST variability (Gordon and Klein, 2014; Ceppi et al., 2016; Manaster et al., 2017). The observationally-constrained SW feedback ranges from –0.91 to –0.46 W m^{-2} °C^{-1} over 40°–70°S depending on the methodology (Ceppi et al., 2016; Terai et al., 2016). In some CMIP6 models, representation of super-cooled liquid water content has been improved, leading to weaker negative optical depth feedback over the Southern Ocean closer to observational estimates (Bodas-Salcedo et al., 2019; Gettelman et al., 2019). This improvement at the same time results in a positive optical depth feedback over other extratropical ocean where LWP decreased in response to reduced stability in those CMIP6 models (Zelinka et al., 2020). Given the accumulated observational estimates and an improved agreement between ESMs and observations, the extratropical optical depth feedback is assessed to be small negative with *medium confidence.* Quantitatively, the global contribution of this feedback is assessed to have a value of -0.03 ± 0.05 W m^{-2} °C^{-1} (one standard deviation) by combining estimates based on observed interannual variability and the cloud controlling factors.

Arctic cloud feedback.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Clouds in polar regions, especially over the Arctic, form at low altitude above or within a stable to neutral boundary layer and are known to co-vary with sea-ice variability beneath. Because the clouds reflect sunlight during summer but trap longwave radiation throughout the year, seasonality plays an important role for cloud effects on Arctic climate (Kay et al., 2016b). AR5 assessed that Arctic low cloud amount will increase in boreal autumn and winter in response to declining sea ice in a warming climate, due primarily to an enhanced upward moisture flux over open water. The cloudier conditions during these seasons result in more downwelling longwave radiation, acting as a positive feedback on surface warming (Kay and Gettelman, 2009). Over recent years, further evidence of the cloud contribution to the Arctic amplification has been obtained (Goosse et al., 2018; Section 7.4.4.1). Space-borne lidar observations show that the cloud response to summer sea-ice loss is small and cannot overcome the cloud effect in autumn (Taylor et al., 2015; Morrison et al., 2018). The seasonality of the cloud response to sea-ice variability is reproduced in GCM simulations (Laîné et al., 2016; Yoshimori et al., 2017). The agreement between observations and models indicates that the Arctic cloud feedback is positive at the surface. This leads to an Arctic cloud feedback at TOA that is *likely* positive, but very small in magnitude as found in some climate models (Pithan and Mauritsen, 2014; Morrison et al., 2018). The observational estimates are sensitive to the analysis period and the choice of reanalysis data, and a recent estimate of the TOA cloud feedback over 60°–90°N using atmospheric reanalysis data and CERES satellite observations suggests a regional value ranging from –0.3 to 0.5 W m^{-2} °C^{-1}, which corresponds to a global contribution of –0.02 to 0.03 W m^{-2} °C^{-1} (Zhang et al., 2018b). Based on the overall agreement between ESMs and observations, the Arctic cloud feedback is assessed small positive and has the value of 0.01 ± 0.05 W m^{-2} °C^{-1} (one standard deviation). The assessed range indicates that a negative feedback is almost as probable as a positive feedback, and the assessment that the Arctic cloud feedback is positive is therefore given *low confidence*.

7.4.2.4.3 Synthesis for the net cloud feedback

The understanding of the response of clouds to warming and associated radiative feedback has deepened since AR5 (Figure 7.9, FAQ7.2). Particular progress has been made in the assessment of the marine low-cloud feedback, which has historically been a major contributor to the cloud feedback uncertainty but is no longer the largest source of uncertainty. Multiple lines of evidence (theory, observations, emergent constraints and process modelling) are now available in addition to ESM simulations, and the positive low-cloud feedback is consequently assessed with *high confidence*.

The best estimate of net cloud feedback is obtained by summing feedbacks associated with individual cloud regimes and assessed to be α_C = 0.42 W m^{-2} °C^{-1}. By assuming that uncertainty of individual cloud feedbacks is independent of each other, their standard deviations are added in quadrature, leading to the *likely* range of 0.12 to 0.72 W m^{-2} °C^{-1} and the *very likely* range of –0.10 to 0.94 W m^{-2} °C^{-1} (Table 7.10). This approach potentially misses feedbacks from cloud regimes that are not assessed, but almost all the major cloud regimes were taken into consideration (Gettelman and Sherwood, 2016) and therefore additional uncertainty will be small. This argument is also supported by an agreement between the net cloud feedback assessed here and the net cloud feedback directly estimated using observations. The observational estimate, which is sensitive to the period considered, based on two atmospheric reanalyses (ERA-Interim and MERRA) and TOA radiation budgets derived from the CERES satellite observations for the years 2000–2010 is 0.54 ± 0.7 W m^{-2} °C^{-1} (one standard deviation) (Dessler, 2013) and overlaps with the assessed range of the net cloud feedback. The assessed *very likely* range is reduced by about 50% compared to AR5, but is still wide compared to those of other climate feedbacks (Table 7.10). The largest contribution to this uncertainty range is the estimate of tropical high-cloud amount feedback which is not yet well quantified using models.

In reality, different types of cloud feedback may occur simultaneously in one cloud regime. For example, an upward shift of high clouds associated with the altitude feedback could be coupled to an increase/decrease of cirrus/anvil cloud fractions associated with the cloud amount feedback. Alternatively, slowdown of the tropical circulation with surface warming (Chapter 4, Section 4.5.3; Figure 7.9) could affect both high and low clouds so that their feedbacks are co-dependent. Quantitative assessments of such covariances require further knowledge about cloud feedback mechanisms, which will further narrow the uncertainty range.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

In summary, deepened understanding of feedback processes in individual cloud regimes since AR5 leads to an assessment of the positive net cloud feedback with *high confidence*. A small probability (less than 10%) of a net negative cloud feedback cannot be ruled out, but this would require an extremely large negative feedback due to decreases in the amount of tropical anvil clouds or increases in optical depth of extratropical clouds over the Southern Ocean; neither is supported by current evidence.

[START TABLE 7.9 HERE]

Table 7.9: Assessed sign and confidence level of cloud feedbacks in difference regimes, compared between AR5 and AR6. For some cloud regimes, the feedback was not assessed in AR5, indicated by N/A.

Feedback	AR5	AR6
High-cloud altitude feedback	Positive (*high confidence*)	Positive (*high confidence*)
Tropical high-cloud amount feedback	N/A	Negative (*low confidence*)
Subtropical marine low-cloud feedback	N/A (*low confidence*)	Positive (*high confidence*)
Land cloud feedback	N/A	Positive (*low confidence*)
Mid-latitude cloud amount feedback	Positive (*medium confidence*)	Positive (*medium confidence*)
Extratropical cloud optical depth feedback	N/A	Small negative (*medium confidence*)
Arctic cloud feedback	Small positive (*very low confidence*)	Small positive (*low confidence*)
Net cloud feedback	Positive (*medium confidence*)	Positive (*high confidence*)

[END TABLE 7.9 HERE]

7.4.2.5 Biogeophysical and non-CO_2 biogeochemical feedbacks

The feedbacks presented in the previous sections (Sections 7.4.2.1–7.4.2.4) are directly linked to physical climate variables (for example temperature, water vapour, clouds, or sea ice). The central role of climate feedbacks associated with these variables has been recognised since early studies of climate change. However, in addition to these physical climate feedbacks, the Earth system includes feedbacks for which the effect of global mean surface temperature change on the TOA energy budget is mediated through other mechanisms, such as the chemical composition of the atmosphere, or by vegetation changes. Among these additional feedbacks, the most important is the CO_2 feedback that describes how a change of the global surface temperature affects the atmospheric CO_2 concentration. In ESM simulations in which CO_2 emissions are prescribed, changes in surface carbon fluxes affect the CO_2 concentration in the atmosphere, the TOA radiative energy budget, and eventually the global mean surface temperature. In ESM simulations in which the CO_2 concentration is prescribed, changes in the carbon cycle allow compatible CO_2 emissions to be calculated, i.e., the CO_2 emissions that are compatible with both the prescribed CO_2 concentration and the representation of the carbon cycle in the ESM. The CO_2 feedback is assessed in Chapter 5, Section 5.4. The framework presented in this chapter assumes that the CO_2 concentration is prescribed, and our assessment of the net feedback parameter, α, does not include carbon-cycle feedbacks on the atmospheric CO_2 concentration (Section 7.1; Box 7.1). However, our assessment of α does include non-CO_2 biogeochemical feedbacks (Section 7.4.2.5.1; including effects due to changes in atmospheric methane concentration) and biogeophysical feedbacks (Section 7.4.2.5.2). A synthesis of the combination of biogeophysical and non-CO_2 biogeochemical feedbacks is given in Section 7.4.2.5.3.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

7.4.2.5.1 Non-CO_2 biogeochemical feedbacks

The chemical composition of the atmosphere (beyond CO_2 and water vapour changes) is expected to change in response to a warming climate. These changes in greenhouse gases (CH_4, N_2O, and ozone) and aerosol amount (including dust) have the potential to alter the TOA energy budget and are collectively referred to as non-CO_2 biogeochemical feedbacks. CH_4 and N_2O feedbacks arise partly from changes in their emissions from natural sources in response to temperature change; these are assessed in Chapter 5, Section 5.4.7 (see also Figure 5.29c). Here we exclude the permafrost CH_4 feedback (Chapter 5, Section 5.4.9.1.2) because, although associated emissions are projected to increase under warming on multi-decadal to centennial timescales, on longer timescales these emissions would eventually substantially decline as the permafrost carbon pools were depleted (Schneider von Deimling et al., 2012, 2015). This leaves the wetland CH_4, land N_2O, and ocean N_2O feedbacks, the assessed mean values of which sum to a positive feedback parameter of +0.04 [0.02 to 0.06] W m^{-2} $°C^{-1}$ (Chapter 5, Section 5.4.7). Other non-CO_2 biogeochemical feedbacks that are relevant to the net feedback parameter are assessed in Chapter 6, Section 6.4.5 (Table 6.8). These feedbacks are associated with sea salt, dimethyl sulphide, dust, ozone, biogenic volatile organic compounds, lightning, and CH_4 lifetime, and sum to a negative feedback parameter of –0.20 [–0.41 to +0.01] W m^{-2} $°C^{-1}$. The overall feedback parameter for non-CO_2 biogeochemical feedbacks is obtained by summing the Chapter 5 and Chapter 6 assessments, which gives –0.16 [–0.37 to +0.05] W m^{-2} $°C^{-1}$. However, there is *low confidence* in the estimates of both the individual non-CO_2 biogeochemical feedbacks as well as their total effect, as evident from the large range in the magnitudes of α from different studies, which can be attributed to diversity in how models account for these feedbacks and limited process-level understanding.

7.4.2.5.2 Biogeophysical feedbacks

Biogeophysical feedbacks are associated with changes in the spatial distribution and/or biophysical properties of vegetation, induced by surface temperature change and attendant hydrological cycle change. These vegetation changes can alter radiative fluxes directly via albedo changes, or via surface momentum or moisture flux changes and hence changes in cloud properties. However, the direct physiological response of vegetation to changes in CO_2, including changes in stomatal conductance, is considered part of the CO_2 effective radiative forcing rather than a feedback (Section 7.3.2.1). The timescale of response of vegetation to climate change is relatively uncertain but can be from decades to hundreds of years (Willeit et al., 2014), and could occur abruptly or as a tipping point (Chapter 5, Section 5.4.9.1.1; Chapter 8, Sections 8.6.2.1 and 8.6.2.2); equilibrium only occurs when the soil system and associated nutrient and carbon pools equilibrate, which can take millennia (Brantley, 2008; Sitch et al., 2008). The overall effects of climate-induced vegetation changes may be comparable in magnitude to those from anthropogenic land-use and land cover change (Davies-Barnard et al., 2015). Climate models that include a dynamical representation of vegetation (e.g., Reick et al., 2013; Harper et al., 2018) are used to explore the importance of biogeophysical feedbacks (Notaro et al., 2007; Brovkin et al., 2009; O'ishi et al., 2009; Port et al., 2012; Willeit et al., 2014; Alo and Anagnostou, 2017; Zhang et al., 2018c; Armstrong et al., 2019). In AR5, it was discussed that such model experiments predicted that expansion of vegetation in the high latitudes of the Northern Hemisphere would enhance warming due to the associated surface albedo change, and that reduction of tropical forests in response to climate change would lead to regional surface warming, due to reduced evapotranspiration (Collins et al., 2013a), but there was no assessment of the associated feedback parameter. SRCCL stated that regional climate change can be dampened or enhanced by changes in local land cover, but that this depends on the location and the season; however, in general the focus was on anthropogenic land cover change, and no assessment of the biogeophysical feedback parameter was carried out. There are also indications of a marine biogeophysical feedback associated with surface albedo change due to changes in phytoplankton (Frouin and Iacobellis, 2002; Park et al., 2015), but there is not currently enough evidence to quantitatively assess this feedback.

Since AR5, several studies have confirmed that a shift from tundra to boreal forests and the associated albedo change leads to increased warming in Northern Hemisphere high latitudes (Willeit et al., 2014; Zhang et al., 2018c; Armstrong et al., 2019) (*high confidence*). However, regional modelling indicates that vegetation feedbacks may act to cool climate in the Mediterranean (Alo and Anagnostou, 2017), and in the tropics and subtropics the regional response is in general not consistent across models. On a global scale, several modelling studies have either carried out a feedback analysis (Stocker et al., 2013; Willeit et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2014) or presented simulations that allow a feedback parameter to be estimated (O'ishi et al., 2009; Armstrong et al., 2019), in such a way that the physiological response can be accounted for as a forcing rather than a feedback. The central estimates of the biogeophysical feedback parameter from these studies range from close to zero (Willeit et al., 2014) to +0.13 W m^{-2} °C^{-1} (Stocker et al., 2013). An additional line of evidence comes from the mid-Pliocene warm period (MPWP, Chapter 2, Cross-Chapter Box 2.1), for which paleoclimate proxies provide evidence of vegetation distribution and CO_2 concentrations. Model simulations that include various combinations of modern versus MPWP vegetation and CO_2 allow an associated feedback parameter to be estimated, as long as account is also taken of the orographic forcing (Lunt et al., 2010, 2012b). This approach has the advantage over pure modelling studies in that the reconstructed vegetation is based on (paleoclimate) observations, and is in equilibrium with the CO_2 forcing. However, there are uncertainties in the vegetation reconstruction in regions with little or no proxy data, and it is uncertain how much of the vegetation change is associated with the physiological response to CO_2. This paleoclimate approach gives an estimate for the biogeophysical feedback parameter of +0.3 W m^{-2} °C^{-1}.

Given the limited number of studies, we take the full range of estimates discussed above for the biogeophysical feedback parameter, and assess the *very likely* range to be from zero to +0.3 W m^{-2} °C^{-1}, with a central estimate of +0.15 W m^{-2} °C^{-1} (*low confidence*). Although this assessment is based on evidence from both models and paleoclimate proxies, and the studies above agree on the sign of the change, there is nonetheless *limited evidence*. Higher confidence could be obtained if there were more studies that allowed calculation of a biogeophysical feedback parameter (particularly from paleoclimates), and if the partitioning between biogeophysical feedbacks and physiological forcing were clearer for all lines of evidence.

7.4.2.5.3 Synthesis of biogeophysical and non-CO_2 biogeochemical feedbacks

The non-CO_2 biogeochemical feedbacks are assessed in Section 7.4.2.5.1 to be –0.16 [–0.37 to +0.05] W m^{-2} °C^{-1} and the biogeophysical feedbacks are assessed in Section 7.4.2.5.2 to be +0.15 [0 to +0.3] W m^{-2} °C^{-1}. The sum of the biogeophysical and non-CO_2 biogeochemical feedbacks is assessed to have a central value of -0.01 W m^{-2} °C^{-1} and a *very likely* range from –0.27 to +0.25 W m^{-2} °C^{-1} (see Table 7.10). Given the relatively long timescales associated with the biological processes that mediate the biogeophysical and many of the non-CO_2 biogeochemical feedbacks, in comparison with the relatively short timescale of many of the underlying model simulations, combined with the small number of studies for some of the feedbacks, and the relatively small signals, this overall assessment has *low confidence*.

Some supporting evidence for this overall assessment can be obtained from the CMIP6 ensemble, which provides some pairs of instantaneous 4×CO_2 simulations carried out using related models with and without biogeophysical and non-CO_2 biogeochemical feedbacks. This is not a direct comparison because these pairs of simulations may differ by more than just their inclusion of these additional feedbacks; furthermore, not all biogeophysical and non-CO_2 biogeochemical feedbacks are fully represented. However, a comparison of the pairs of simulations does provide a first-order estimate of the magnitude of these additional feedbacks. Séférian et al. (2019) find a slightly more negative feedback parameter in CNRM-ESM2-1 (with additional feedbacks) then in CNRM-CM6-1 (a decrease of 0.02 W m^{-2} °C^{-1}, using the linear regression method from years 10-150). Andrews et al. (2019) also find a slightly more negative feedback parameter when these additional feedbacks are included (a decrease of 0.04 W m^{-2}°C^{-1} in UKESM1 compared with HadGEM3-GC3.1). Both of these studies suggest a small but slightly negative feedback parameter for the combination of biogeophysical and non-CO_2 biogeochemical feedbacks, but with relatively large uncertainty given (a) interannual variability and (b) that feedbacks associated with natural terrestrial emissions of CH_4 and N_2O were not represented in either pair.

7.4.2.6 Long term radiative feedbacks associated with ice sheets

Although long-term radiative feedbacks associated with ice sheets are not included in our definition of ECS (Box 7.1), the relevant feedback parameter is assessed here because the timescales on which these feedbacks act are relatively uncertain, and the long-term temperature response to CO_2 forcing of the entire Earth system may be of interest.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Earth's ice sheets (Greenland and Antarctica) are sensitive to climate change (Chapter 9, Section 9.4; Pattyn et al., 2018). Their time evolution is determined by both their surface mass balance and ice dynamic processes, with the latter being particularly important for the West Antarctic Ice Sheet. Surface mass balance depends on the net energy and hydrological fluxes at their surface, and there are mechanisms of ice sheet instability that depend on ocean temperatures and basal melt rates (Chapter 9, Section 9.4.1.1). The presence of ice sheets affects Earth's radiative budget, hydrology, and atmospheric circulation due to their characteristic high albedo, low roughness length, and high altitude, and they influence ocean circulation through freshwater input from calving and melt (e.g., Fyke et al., 2018). Ice sheet changes also modify surface albedo through the attendant change in sea level and therefore land area (Abe-Ouchi et al., 2015). The timescale for ice sheets to reach equilibrium is on the order of thousands of years (Clark et al., 2016). Due to the long timescales involved, it is a major challenge to run coupled climate-ice sheet models to equilibrium, and as a result, long-term simulations are often carried out with lower complexity models, and/or are asynchronously coupled.

In AR5, it was described that both the Greenland and Antarctic ice sheets would continue to lose mass in a warming world (Collins et al., 2013a), with a continuation in sea level rise beyond the year 2500 assessed as *virtually certain*. However, there was *low confidence* in the associated radiative feedback mechanisms, and as such, there was no assessment of the magnitude of long-term radiative feedbacks associated with ice sheets. That assessment is consistent with SROCC, wherein it was stated that 'with limited published studies to draw from and no simulations run beyond 2100, firm conclusions regarding the net importance of atmospheric versus ocean melt feedbacks on the long-term future of Antarctica cannot be made.'

The magnitude of the radiative feedback associated with changes to ice sheets can be quantified by comparing the global mean long-term equilibrium temperature response to increased CO_2 concentrations in simulations that include interactive ice sheets with that of simulations that do not include the associated ice-sheet climate interactions (Swingedouw et al., 2008; Vizcaíno et al., 2010; Goelzer et al., 2011; Bronselaer et al., 2018; Golledge et al., 2019). These simulations indicate that on multi-centennial timescales, ice sheet mass loss leads to fresh water fluxes that can modify ocean circulation (Swingedouw et al., 2008; Goelzer et al., 2011; Bronselaer et al., 2018; Golledge et al., 2019). This leads to reduced surface warming (by about 0.2°C in the global mean after 1000 years; Goelzer et al., 2011; see also Section 7.4.4.1.1), although other work suggests no net global temperature effect of ice sheet mass loss (Vizcaíno et al., 2010). However, model simulations in which the Antarctic ice sheet is removed completely in a paleoclimate context indicate a positive global mean feedback on multi-millennial timescales due primarily to the surface albedo change (Goldner et al., 2014a; Kennedy-Asser et al., 2019); in Chapter 9 (Section 9.6.3) it is assessed that such ice-free conditions could eventually occur given 7–13°C of warming. This net positive feedback due to ice sheets on long timescales is also supported by model simulations of the mid-Pliocene warm period (MPWP, Chapter 2, Cross-chapter Box 2.1) in which the volume and area of the Greenland and West Antarctic ice sheets are reduced in model simulations in agreement with geological data (Chandan and Peltier, 2018), leading to surface warming. As such, overall, on multi-centennial timescales the feedback parameter associated with ice sheets is *likely* negative (*medium confidence*), but on multi-millennial timescales by the time the ice sheets reach equilibrium, the feedback parameter is *very likely* positive (*high confidence*; see Table 7.10). However, a relative lack of models carrying out simulations with and without interactive ice sheets over centennial to millennial timescales means that there is currently not enough evidence to quantify the magnitude of these feedbacks, or the timescales on which they act.

7.4.2.7 Synthesis

Table 7.10 summarises the estimates and the assessment of the individual and the net feedbacks presented in the above sections. The uncertainty range of the net climate feedback was obtained by adding standard deviations of individual feedbacks in quadrature, assuming that they are independent and follow the Gaussian distribution. It is *virtually certain* that the net climate feedback is negative, primarily due to the Planck temperature response, indicating that climate acts to stabilise in response to radiative forcing imposed to the system. Supported by the level of confidence associated with the individual feedbacks, it is also

ACCEPTED VERSION SUBJECT TO FINAL EDITING

virtually certain that the sum of the non-Planck feedbacks is positive. Based on Table 7.10 these climate feedbacks amplify the Planck temperature response by about 2.8 [1.9 to 5.9] times. Cloud feedback remains the largest contributor to uncertainty of the net feedback, but the uncertainty is reduced compared to AR5. A secondary contribution to the net feedback uncertainty is the biogeophysical and non-CO_2 biogeochemical feedbacks, which together are assessed to have a central value near zero and thus do not affect the central estimate of ECS. The net climate feedback is assessed to be –1.16 W m^{-2} °C^{-1}, *likely* from –1.54 to –0.78 W m^{-2} °C^{-1}, and *very likely* from –1.81 to –0.51 W m^{-2}°C^{-1}.

Feedback parameters in climate models are calculated assuming that they are independent of each other, except for a well-known co-dependency between the WV and LR feedbacks. When the inter-model spread of the net climate feedback is computed by adding in quadrature the inter-model spread of individual feedbacks, it is 17% wider than the spread of the net climate feedback directly derived from the ensemble. This indicates that the feedbacks in climate models are partly co-dependent. Two possible co-dependencies have been suggested (Huybers, 2010; Caldwell et al., 2016). One is a negative covariance between the LR and longwave cloud feedbacks, which may be accompanied by a deepening of the troposphere (O'Gorman and Singh, 2013; Yoshimori et al., 2020) leading both to greater rising of high clouds and a larger upper-tropospheric warming. The other is a negative covariance between albedo and shortwave cloud feedbacks, which may originate from the Arctic regions: a reduction in sea ice enhances the shortwave cloud radiative effect because the ocean surface is darker than sea ice (Gilgen et al., 2018). This covariance is reinforced as the decrease of sea-ice leads to an increase in low-level clouds (Mauritsen et al., 2013). However, the mechanism causing these co-dependences between feedbacks is not well understood yet and a quantitative assessment based on multiple lines of evidence is difficult. Therefore, this synthesis assessment does not consider any co-dependency across individual feedbacks.

The assessment of the net climate feedback presented above is based on a single approach (i.e., process understanding) and directly results in a value for ECS given in Section 7.5.1; this is in contrast to the synthesis assessment of ECS in Section 7.5.5 which combines multiple approaches. The total (net) feedback parameter consistent with the final synthesis assessment of the ECS and Equation 7.1 is provided there.

7.4.2.8 Climate feedbacks in ESMs

Since AR5, many modelling groups have newly participated in CMIP experiments, leading to an increase in the number of models in CMIP6 (Chapter 1, Section 1.5.4). Other modelling groups that contributed to CMIP5 also updated their ESMs for carrying out CMIP6 experiments. While some of the CMIP6 models share components and are therefore not independent, they are analysed independently when calculating climate feedbacks. This, and more subtle forms of model inter-dependence, creates challenges when determining appropriate model weighting schemes (Chapter 1, Section 1.5.4). Additionally, it must be kept in mind that the ensemble sizes of the CMIP5 and CMIP6 models are not sufficiently large to sample the full range of model uncertainty.

The multi-model mean values of all physical climate feedbacks are calculated using the radiative kernel method (Section 7.4.1) and compared with the assessment in the previous sections (Figure 7.10). For CMIP models, there is a discrepancy between the net climate feedback calculated directly using the time evolutions of ΔT and ΔN in each model and the accumulation of individual feedbacks, but it is negligibly small (Supplementary Material 7.SM.4). Feedbacks due to biogeophysical and non-CO_2 biogeochemical processes are included in some models but neglected in the kernel analysis. In the AR6, biogeophysical and non-CO_2 biogeochemical feedbacks are explicitly assessed (Section 7.4.2.5).

All the physical climate feedbacks apart from clouds are very similar to each other in CMIP5 and CMIP6 model ensembles (see also Table 7.10). These values, where possible supported by other lines of evidence, are used for assessing feedbacks in Sections 7.4.2.1–7.4.2.3. A difference found between CMIP5 and CMIP6 models is the net cloud feedback, which is larger in CMIP6 by about 20%. This change is the major cause of less-negative values of the net climate feedback in CMIP6 than in CMIP5 and hence an increase in modelled ECS (Section 7.5.1).

A remarkable improvement of cloud representation in some CMIP6 models is the reduced error of the too weak negative SW CRE over the Southern Ocean (Bodas-Salcedo et al., 2019; Gettelman et al., 2019) due to a more realistic simulation of supercooled liquid droplets and associated cloud optical depths that were biased low commonly in CMIP5 models (McCoy et al. 2014a; 2014b). Because the negative cloud optical depth feedback occurs due to 'brightening' of clouds via phase change from ice to liquid cloud particles in response to surface warming (Cesana and Storelvmo, 2017), the extratropical cloud SW feedback tends to be less negative or even slightly positive in models with reduced errors (Bjordal et al., 2020; Zelinka et al., 2020). The assessment of cloud feedbacks in Section 7.4.2.4 incorporates estimates from these improved ESMs. Yet, there still remain other shared model errors such as in the subtropical low clouds (Calisto et al., 2014) and tropical anvil clouds (Mauritsen and Stevens, 2015), hampering an assessment of feedbacks associated with these cloud regimes based only on ESMs (Section 7.4.2.4).

[START FIGURE 7.10 HERE]

Figure 7.10: Global-mean climate feedbacks estimated in *abrupt4xCO2* simulations of 29 CMIP5 models (light blue) and 49 CMIP6 models (orange), compared with those assessed in this Report (red). Individual feedbacks for CMIP models are averaged across six radiative kernels as computed in Zelinka et al. (2020). The white line, black box and vertical line indicate the mean, 66% and 90% ranges, respectively. The shading represents the probability distribution across the full range of GCM/ESM values and for the 2.5-97.5 percentile range of the AR6 normal distribution. The unit is W m^{-2} °C^{-1}. Feedbacks associated with biogeophysical and non-CO_2 biogeochemical processes are assessed in AR6, but they are not explicitly estimated from GCMs/ESMs in CMIP5 and CMIP6. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

7.4.3 Dependence of feedbacks on climate mean state

In the standard framework of forcings and feedbacks (Section 7.4.1; Box 7.1), the approximation is made that the strength of climate feedbacks is independent of the background global surface mean temperature. More generally, the individual feedback parameters, α_x, are often assumed to be constant over a range of climate states, including those reconstructed from the past (encompassing a range of states warmer and colder than today, with varying continental geographies) or projected for the future. If this approximation holds, then the equilibrium global surface temperature response to a fixed radiative forcing will be constant, regardless of the climate state to which that forcing is applied.

This approximation will break down if climate feedbacks are not constant, but instead vary as a function of, e.g., background temperature (Roe and Baker, 2007; Zaliapin and Ghil, 2010; Roe and Armour, 2011; Bloch-Johnson et al., 2015), continental configuration (Farnsworth et al., 2019), or configuration of ice sheets (Yoshimori et al., 2009). If the real climate system exhibits this state dependence, then the future equilibrium temperature change in response to large forcing may be different from that inferred using the standard framework, and/or different to that inferred from paleoclimates. Such considerations are important for the assessment of ECS (Section 7.5). Climate models generally include representations of feedbacks that allow state-dependent behaviour, and so model results may also differ from the predictions from the standard framework.

In AR5 (Boucher et al., 2013), there was a recognition that climate feedbacks could be state dependent (Colman and McAvaney, 2009), but modelling studies that explored this (e.g., Manabe and Bryan, 1985; Voss and Mikolajewicz, 2001; Stouffer and Manabe, 2003; Hansen, 2005b) were not assessed in detail. Also in AR5 (Masson-Delmotte et al., 2013), it was assessed that some models exhibited weaker sensitivity to Last Glacial Maximum (LGM, Cross-Chapter Box 2.1) forcing than to $4\times CO_2$ forcing, due to state-dependence in shortwave cloud feedbacks.

Here, recent evidence for state-dependence in feedbacks from modelling studies (Section 7.4.3.1) and from the paleoclimate record (Section 7.4.3.2) are assessed, with an overall assessment in Section 7.4.3.3. The focus is on temperature-dependence of feedbacks when the system is in equilibrium with the forcing; evidence for transient changes in the net feedback parameter associated with evolving spatial patterns of warming is assessed separately in Section 7.4.4.

7.4.3.1 State-dependence of feedbacks in models

There are several modelling studies since AR5 in which ESMs of varying complexity have been used to explore temperature dependence of feedbacks, either under modern (Hansen et al., 2013; Jonko et al., 2013; Meraner et al., 2013; Good et al., 2015; Duan et al., 2019; Mauritsen et al., 2019; Rohrschneider et al., 2019; Rugenstein et al., 2019b; Stolpe et al., 2019; Bloch-Johnson et al., 2020) or paleo (Caballero and Huber, 2013; Zhu et al., 2019b) climate conditions, typically by carrying out multiple simulations across successive CO_2 doublings. A non-linear temperature response to these successive doublings may be partly due to forcing that increases more (or less) than expected from a purely logarithmic dependence (Section 7.3.2; Etminan et al., 2016), and partly due to state-dependence in feedbacks; however, not all modelling studies have partitioned the non-linearities in temperature response between these two effects. Nonetheless, there is general agreement amongst ESMs that the net feedback parameter, α, increases (i.e., becomes less negative) as temperature increases from pre-industrial levels (i.e., sensitivity to forcing increases as temperature increases; e.g., Meraner et al., 2013; see Figure 7.11). The associated increase in sensitivity to forcing is, in most models, due to the water vapour (Section 7.4.2.2) and cloud (Section 7.4.2.4) feedback parameters increasing with warming (Caballero and Huber, 2013; Meraner et al., 2013; Rugenstein et al., 2019b; Zhu et al., 2019b; Sherwood et al., 2020b). These changes are offset partially by the surface albedo feedback

ACCEPTED VERSION SUBJECT TO FINAL EDITING

parameter decreasing (Jonko et al., 2013; Meraner et al., 2013; Rugenstein et al., 2019b), as a consequence of a reduced amount of snow and sea ice cover in a much warmer climate. At the same time, there is little change in the Planck response (Section 7.4.2.1), which has been shown in one model to be due to competing effects from increasing Planck emission at warmer temperatures and decreasing planetary emissivity due to increased CO_2 and water vapour (Mauritsen et al., 2019). Analysis of the spatial patterns of the non-linearities in temperature response (Good et al., 2015) suggests that these patterns are linked to a reduced weakening of the AMOC, and changes to evapotranspiration. The temperature dependence of α is also found in model simulations of high-CO_2 paleoclimates (Caballero and Huber, 2013; Zhu et al., 2019b). The temperature dependence is not only evident at very high CO_2 concentrations in excess of $4\times CO_2$, but also apparent in the difference in temperature response to a $2\times CO_2$ forcing compared with to a $4\times CO_2$ forcing (Mauritsen et al., 2019; Rugenstein et al., 2019b), and as such is relevant for interpreting century-scale climate projections.

Despite the general agreement that α increases as temperature increases from pre-industrial levels (Figure 7.11), other modelling studies have found the opposite (Duan et al., 2019; Stolpe et al., 2019). Modelling studies exploring state dependence in climates colder than today, including in cold paleoclimates such as the LGM, provide conflicting evidence of either decreased (Yoshimori et al., 2011) or increased (Kutzbach et al., 2013; Stolpe et al., 2019) temperature response per unit forcing during cold climates compared to the modern era.

In contrast to most ESMs, the majority of Earth system models of intermediate complexity (EMICs) do not exhibit state dependence, or have a net feedback parameter that decreases with increasing temperature (Pfister and Stocker, 2017). This is unsurprising since EMICs usually do not include process-based representations of water vapour and cloud feedbacks. Although this shows that care must be taken when interpreting results from current generation EMICs, Pfister and Stocker (2017) also suggest that non-linearities in feedbacks can take a long time to emerge in model simulations due slow adjustment timescales associated with the ocean; longer simulations also allow better estimates of equilibrium warming (Bloch-Johnson et al., 2020). This implies that multi-century simulations (Rugenstein et al., 2019b) could increase confidence in ESM studies examining state dependence.

The possibility of more substantial changes in climate feedbacks, sometimes accompanied by hysteresis and/or irreversibility, has been suggested from some theoretical and modelling studies. It has been postulated that such changes could occur on a global scale and across relatively narrow temperature changes (Popp et al., 2016; von der Heydt and Ashwin, 2016; Steffen et al., 2018; Schneider et al., 2019; Ashwin and von der Heydt, 2020; Bjordal et al., 2020). However, the associated mechanisms are highly uncertain, and as such there is *low confidence* as to whether such behaviour exists at all, and in the temperature thresholds at which it might occur.

Overall, the modelling evidence indicates that there is *medium confidence* that the net feedback parameter, α, increases (i.e., becomes less negative) with increasing temperature (i.e., that sensitivity to forcing increases with increasing temperature), under global surface background temperatures at least up to 40°C (Meraner et al., 2013; Seeley and Jeevanjee, 2021), and *medium confidence* that this temperature dependence primarily derives from increases in the water vapour and shortwave cloud feedbacks. This assessment is further supported by recent analysis of CMIP6 model simulations (Bloch-Johnson et al., 2020) in the framework of nonlinMIP (Good et al., 2016), which showed that out of ten CMIP6 models, seven of them showed an increase of the net feedback parameter with temperature, primarily due to the water vapour feedback.

7.4.3.2 State-dependence of feedbacks in the paleoclimate proxy record

Several studies have estimated ECS from observations of the glacial-interglacial cycles of the last approximately 2 million years, and found a state dependence, with more-negative α (i.e., lower sensitivity to forcing) during colder periods of the cycles and less-negative α during warmer periods (von der Heydt et al., 2014; Köhler et al., 2015, 2017; Friedrich et al., 2016; Royer, 2016; Snyder, 2019); see summaries in Skinner (2012) and von der Heydt et al. (2016). However, the nature of the state dependence derived from

ACCEPTED VERSION SUBJECT TO FINAL EDITING

these observations is dependent on the assumed ice sheet forcing (Köhler et al., 2015; Stap et al., 2019), which is not well known, due to a relative lack of proxy indicators of ice sheet extent and distribution prior to the LGM (Cross-Chapter Box 2.1). Furthermore, many of these glacial-interglacial studies estimate a very strong temperature-dependence of α (Figure 7.11) that is hard to reconcile with the other lines of evidence, including proxy estimates from warmer paleoclimates. However, if the analysis excludes time periods when the temperature and CO_2 data are not well correlated, which occurs in general at times when sea level is falling and obliquity is decreasing, the state-dependence reduces (Köhler et al., 2018). Despite these uncertainties, due to the agreement in the sign of the temperature-dependence from all these studies, there is *medium confidence* from the paleoclimate proxy record that the net feedback parameter, α, was less negative in the warm periods than in the cold periods of the glacial-interglacial cycles.

Paleoclimate proxy evidence from past high-CO_2 time periods much warmer than present (the early Eocene and PETM; Cross-Chapter Box 2.1) show that the feedback parameter increases as temperature increases (Anagnostou et al., 2016, 2020; Shaffer et al., 2016). However, such temperature-dependence of feedbacks was not found in the warm Pliocene relative to the cooler Pleistocene (Martínez-Botí et al., 2015), although the temperature changes are relatively small at this time, making temperature-dependence challenging to detect given the uncertainties in reconstructing global mean temperature and forcing. Overall, the paleoclimate proxy record provides *medium confidence* that the net feedback parameter, α, was less negative in these past warm periods than in the present day.

7.4.3.3 Synthesis of state-dependence of feedbacks from modelling and paleoclimate records

Overall, independent lines of evidence from models (Section 7.4.3.1) and from the paleoclimate proxy record (Section 7.4.3.2) lead to *high confidence* that the net feedback parameter, α, increases (i.e., becomes less negative) as temperature increases; i.e., that sensitivity to forcing increases as temperature increases; see Figure 7.11. This temperature-dependence should be considered when estimating ECS from ESM simulations in which CO_2 is quadrupled (Section 7.5.5) or from paleoclimate observations from past time periods colder or warmer than today (Section 7.5.4). Although individual lines of evidence give only *medium confidence*, the overall high confidence comes from the multiple models that show the same sign of the temperature-dependence of α, the general agreement in evidence from the paleo proxy and modelling lines of evidence, and the agreement between proxy evidence from both cold and warm past climates. However, due to the large range in estimates of the magnitude of the temperature-dependence of α across studies (Figure 7.11), a quantitative assessment cannot currently be given, which provides a challenge for including this temperature-dependence in emulator-based future projections (Cross-Chapter Box 7.1). Greater confidence in the modelling lines of evidence could be obtained from simulations carried out for several hundreds of years (Rugenstein et al., 2019b), substantially longer than in many studies, and from more models carrying out simulations at multiple CO_2 concentrations. Greater confidence in the paleoclimate lines of evidence would be obtained from stronger constraints on atmospheric CO_2 concentrations, ice sheet forcing, and temperatures, during past warm climates.

[START FIGURE 7.11 HERE]

Figure 7.11: Feedback parameter, α (W m^{-2} °C^{-1}), as a function of global mean surface air temperature anomaly relative to preindustrial, for ESM simulations (red circles and lines) (Caballero and Huber, 2013; Jonko et al., 2013; Meraner et al., 2013; Good et al., 2015; Duan et al., 2019; Mauritsen et al., 2019; Stolpe et al., 2019; Zhu et al., 2019b), **and derived from paleoclimate proxies (grey squares and lines)** (von der Heydt et al., 2014; Anagnostou et al., 2016, 2020; Friedrich et al., 2016; Royer, 2016; Shaffer et al., 2016; Köhler et al., 2017; Snyder, 2019; Stap et al., 2019). For the ESM simulations, the value on the *x*-axis refers to the average of the temperature before and after the system has equilibrated to a forcing (in most cases a CO_2 doubling), and is expressed as an anomaly relative to an associated pre-industrial global mean temperature from that model. The light blue shaded square extends across the assessed range of α (Table 7.10) on the *y*-axis, and on the *x*-axis extends across the approximate temperature range over which the assessment of α is based (taken as from zero to the assessed central value of ECS (Table 7.13). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.11 HERE]

7.4.4 Relationship between feedbacks and temperature patterns

The large-scale patterns of surface warming in observations since the 19th century (Chapter 2, Section 2.3.1) and climate model simulations (Chapter 4, Section 4.3.1; Figure 7.12a) share several common features. In particular, surface warming in the Arctic is greater than for the global average and greater than in the southern hemisphere (SH) high latitudes; and surface warming is generally greater over land than over the ocean. Observations and climate model simulations also show some notable differences. ESMs generally simulate a weakening of the equatorial Pacific Ocean zonal (east-west) SST gradient on multi-decadal to centennial timescales, with greater warming in the east than the west, but this trend has not been seen in observations (Chapter 2, Figure 2.11b; Chapter 9, Section 9.2.1).

Chapter 4, Section 4.5.1 discusses patterns of surface warming for 21st century climate projections under the Shared Socioeconomic Pathways (SSP) scenarios. Chapter 9, Section 9.2.1 assesses historical SST trends and the ability of coupled ESMs to replicate the observed changes. Chapter 4, Section 4.5.1 discusses the processes that cause the land to warm more than the ocean (land-ocean warming contrast). This section assesses process understanding of the large-scale patterns of surface temperature response from the perspective of a regional energy budget. It then assesses evidence from the paleoclimate proxy record for patterns of surface warming during past time periods associated with changes in atmospheric CO_2 concentrations. Finally, it assesses how radiative feedbacks depend on the spatial pattern of surface temperature, and thus how they can change in magnitude as that pattern evolves over time, with implications for the assessment of ECS based on historical warming (Sections 7.4.4.3 and 7.5.2.1).

7.4.4.1 Polar amplification

Polar amplification describes the phenomenon where surface temperature change at high latitudes exceeds the global average surface temperature change in response to radiative forcing of the climate system. Arctic amplification, often defined as the ratio of Arctic to global surface warming, is a ubiquitous emergent feature of climate model simulations (Holland and Bitz, 2003; Pithan and Mauritsen, 2014; Chapter 4, Section 4.5.1; Figure 7.12a) and is also seen in observations (Chapter 2, Section 2.3.1). However, both climate models and observations show relatively less warming of the SH high latitudes compared to the northern hemisphere (NH) high latitudes over the historical record (Chapter 2, Section 2.3.1); a characteristic that is projected to continue over the 21st century (Chapter 4, Section 4.5.1). Since AR5 there is a much-improved understanding of the processes that drive polar amplification in the NH and delay its emergence in the SH (Section 7.4.4.1.1). Furthermore, the paleoclimate record provides evidence for polar amplification from multiple time periods associated with changes in CO_2 (Hollis et al., 2019; Cleator et al., 2020; McClymont et al., 2020; Tierney et al., 2020b), and allows an evaluation of polar amplification in model simulations of these periods (Section 7.4.4.1.2). Research since AR5 identifies changes in the degree of polar amplification over time, particularly in the SH, as a key factor affecting how radiative feedbacks may evolve in the future (Section 7.4.4.3).

[START FIGURE 7.12 HERE]

(b-d) Contributions to net Arctic (>60°N), tropical (30°S – 30°N), and Antarctic (<60°S) warming calculated by dividing regional-average energy inputs by the magnitude of the regional-average Planck response. The contributions from radiative forcing, changes in moist, dry-static, and total atmospheric energy transport, ocean heat uptake, and radiative feedbacks (orange bars) all sum to the value of net warming (grey bar). Inset shows regional warming contributions associated with individual feedbacks, all summing to the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

total feedback contribution. Uncertainties show the interquartile range (25th and 75th percentiles) across models. The warming contributions (units of °C) for each process are diagnosed by calculating the energy flux (units of W m^{-2}) that each process contributes to the atmosphere over a given region, either at the TOA or surface, then dividing that energy flux by the magnitude of the regional Planck response (around 3.2 W m^{-2} $°C^{-1}$ but varying with region). By construction, the individual warming contributions sum to the total warming in each region. Radiative kernel methods (see Section 7.4.1) are used to decompose the net energy input from radiative feedbacks into contributions from changes in atmospheric water vapour, lapse-rate, clouds, and surface albedo (Zelinka et al. (2020) using the Huang et al. (2017) radiative kernel). The CMIP6 models included are those analysed by Zelinka et al. (2020) and the warming contribution analysis is based on that of Goosse et al. (2018). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.12 HERE]

7.4.4.1.1 Critical processes driving polar amplification

Several processes contribute to polar amplification under greenhouse gas forcing including the loss of sea ice and snow (an amplifying surface-albedo feedback), the confinement of warming to near the surface in the polar atmosphere (an amplifying lapse-rate feedback), and increases in poleward atmospheric and oceanic heat transport (Pithan and Mauritsen, 2014; Goosse et al., 2018; Dai et al., 2019; Feldl et al., 2020). Modelling and process studies since AR5 have led to an improved understanding of the combined effect of these different processes in driving polar amplification and how they differ between the hemispheres.

Idealized modelling studies suggest that polar amplification would occur even in the absence of any amplifying polar surface-albedo or lapse-rate feedbacks owing to changes in poleward atmospheric heat transport under global warming (Hall, 2004; Alexeev et al., 2005; Graversen and Wang, 2009; Alexeev and Jackson, 2013; Graversen et al., 2014; Roe et al., 2015; Merlis and Henry, 2018; Armour et al., 2019). Poleward heat transport changes reflect compensating changes in the transport of latent energy (moisture) and dry-static energy (sum of sensible and potential energy) by atmospheric circulations (Alexeev et al., 2005; Held and Soden, 2006; Hwang and Frierson, 2010; Hwang et al., 2011; Kay et al., 2012; Huang and Zhang, 2014; Feldl et al., 2017a; Donohoe et al., 2020). ESMs project that within the mid-latitudes, where eddies dominate the heat transport, an increase in poleward latent energy transport arises from an increase in the equator-to-pole gradient in atmospheric moisture with global warming, with moisture in the tropics increasing more than at the poles as described by the Clausius-Clapeyron relation (Chapter 8, Section 8.2). This change is partially compensated by a decrease in dry-static energy transport arising from a weakening of the equator-to-pole temperature gradient as the polar regions warm more than the tropics.

Energy balance models that approximate atmospheric heat transport in terms of a diffusive flux down the meridional gradient of near-surface moist static energy (sum of dry-static and latent energy) are able to reproduce the atmospheric heat transport changes seen within ESMs (Flannery, 1984; Hwang and Frierson, 2010; Hwang et al., 2011; Rose et al., 2014; Roe et al., 2015; Merlis and Henry, 2018), including the partitioning of latent and dry-static energy transports (Siler et al., 2018b; Armour et al., 2019). These models suggest that polar amplification is driven by enhanced poleward latent heat transport and that the magnitude of polar amplification can be enhanced or diminished by the latitudinal structure of radiative feedbacks. Amplifying polar feedbacks enhance polar warming and in turn cause a decrease in the dry-static energy transport to high latitudes (Alexeev and Jackson, 2013; Rose et al., 2014; Roe et al., 2015; Bonan et al., 2018; Merlis and Henry, 2018; Armour et al., 2019; Russotto and Biasutti, 2020). Poleward latent heat transport changes act to favour polar amplification and inhibit tropical amplification (Armour et al., 2019), resulting in a strongly polar-amplified warming response to polar forcing and a more latitudinally-uniform warming response to tropical forcing within ESMs (Alexeev et al., 2005; Rose et al., 2014; Stuecker et al., 2018). The important role for poleward latent energy transport in polar amplification is supported by studies of atmospheric reanalyses and ESMs showing that episodic increases in latent heat transport into the Arctic can enhance surface downwelling radiation and drive sea-ice loss on sub-seasonal timescales (Woods and Caballero, 2016; Gong et al., 2017; Lee et al., 2017; Luo et al., 2017a), however this may be a smaller driver of sea-ice variability than atmospheric temperature fluctuations (Olonscheck et al., 2019).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Regional energy budget analyses are commonly used to diagnose the relative contributions of radiative feedbacks and energy fluxes to polar amplification as projected by ESMs under increased CO_2 concentrations (Figure 7.12; Feldl and Roe, 2013; Pithan and Mauritsen, 2014; Goosse et al., 2018; Stuecker et al., 2018). These analyses suggest that a primary cause of amplified Arctic warming in ESMs is the latitudinal structure of radiative feedbacks, which warm the Arctic more than the tropics (Figure 7.12b), and enhanced latent energy transport into the Arctic. That net atmospheric heat transport into the Arctic does not change substantially within ESMs, on average, under CO_2 forcing (Figure 7.12b) reflects a compensating decrease in poleward dry-static energy transport as a response to polar amplified warming (Hwang et al., 2011; Armour et al., 2019; Donohoe et al., 2020). The latitudinal structure of radiative feedbacks primarily reflects that of the surface-albedo and lapse-rate feedbacks, which preferentially warm the Arctic (Graversen et al., 2014; Pithan and Mauritsen, 2014; Goosse et al., 2018). Latitudinal structure in the lapse-rate feedback reflects weak radiative damping to space with surface warming in polar regions, where atmospheric warming is constrained to the lower troposphere owing to stably stratified conditions, and strong radiative damping in the tropics, where warming is enhanced in the upper troposphere owing to moist convective processes. This is only partially compensated by latitudinal structure in the water vapour feedback (Taylor et al., 2013), which favours tropical warming (Pithan and Mauritsen, 2014). While cloud feedbacks have been found to play little role in Arctic amplification in CMIP5 models (Pithan and Mauritsen, 2014; Goosse et al., 2018; Figure 7.12b), less-negative cloud feedbacks at high latitude as seen within some CMIP6 models (Zelinka et al., 2020) tend to favour stronger polar amplification (Dong et al., 2020). A weaker Planck response at high latitudes, owing to less efficient radiative damping where surface and atmospheric temperatures are lower, also contributes to polar amplification (Pithan and Mauritsen, 2014). The effective radiative forcing of CO_2 is larger in the tropics than at high latitudes, suggesting that warming would be tropically amplified if not for radiative feedbacks and poleward latent heat transport changes (Stuecker et al., 2018; Figure 7.12b-d).

While the contributions to regional warming can be diagnosed within ESM simulations (Figure 7.12), assessment of the underlying role of individual factors is limited by interactions inherent to the coupled climate system. For example, polar feedback processes are coupled and influenced by warming at lower latitudes (Screen et al., 2012; Alexeev and Jackson, 2013; Graversen et al., 2014; Graversen and Burtu, 2016; Rose and Rencurrel, 2016; Feldl et al., 2017a; Yoshimori et al., 2017; Garuba et al., 2018; Po-Chedley et al., 2018a; Stuecker et al., 2018; Dai et al., 2019; Feldl et al., 2020), while atmospheric heat transport changes are in turn influenced by the latitudinal structure of regional feedbacks, radiative forcing, and ocean heat uptake (Hwang et al., 2011; Zelinka and Hartmann, 2012; Feldl and Roe, 2013; Huang and Zhang, 2014; Merlis, 2014; Rose et al., 2014; Roe et al., 2015; Feldl et al., 2017b; Stuecker et al., 2018; Armour et al., 2019). The use of different feedback definitions, such as a lapse-rate feedback partitioned into upper and lower tropospheric components (Feldl et al., 2020) or including the influence of water vapour at constant relative humidity (Held and Shell, 2012; Section 7.4.2), would also change the interpretation of which feedbacks contribute most to polar amplification.

The energy budget analyses (Figure 7.12) suggest that greater surface warming in the Arctic than the Antarctic under greenhouse gas forcing arises from two main processes. The first is large surface heat uptake in the Southern Ocean (Figure 7.12c) driven by the upwelling of deep waters that have not yet felt the effects of the radiative forcing; the heat taken up is predominantly transported away from Antarctica by northward-flowing surface waters (Marshall et al., 2015; Armour et al., 2016; Chapter 9, Section 9.2.1). Strong surface heat uptake also occurs in the subpolar North Atlantic Ocean under global warming (Chapter 9, Section 9.2.1). However, this heat is partially transported northward into the Arctic which leads to increased heat fluxes into the Arctic atmosphere (Rugenstein et al., 2013; Jungclaus et al., 2014; Koenigk and Brodeau, 2014; Marshall et al., 2015; Nummelin et al., 2017; Singh et al., 2017; Oldenburg et al., 2018; Figure 7.12b). The second main process contributing to differences in Arctic and Antarctic warming is the asymmetry in radiative feedbacks between the poles (Yoshimori et al., 2017; Goosse et al., 2018). This primarily reflects the weaker lapse-rate and surface-albedo feedbacks and more-negative cloud feedbacks in the SH high latitudes (Figure 7.12). However, note the SH cloud feedbacks are uncertain due to possible biases in the treatment of mixed phase clouds (Hyder et al., 2018). Idealized modelling suggests that the asymmetry in the polar lapse-rate feedback arises from the height of the Antarctic ice sheet precluding the formation of deep atmospheric inversions that are necessary to produce the stronger positive lapse-rate feedbacks seen in the Arctic (Salzmann, 2017; Hahn et al., 2020). ESM projections of the equilibrium response to CO_2 forcing

ACCEPTED VERSION SUBJECT TO FINAL EDITING

show polar amplification in both hemispheres, but generally with less warming in the Antarctic than the Arctic (Li et al., 2013a; Yoshimori et al., 2017).

Because multiple processes contribute to polar amplification, it is a robust feature of the projected long-term response to greenhouse gas forcing in both hemispheres. At the same time, contributions from multiple processes make projections of the magnitude of polar warming inherently more uncertain than global mean warming (Holland and Bitz, 2003; Roe et al., 2015; Bonan et al., 2018; Stuecker et al., 2018). The magnitude of Arctic amplification ranges from a factor of two to four in ESM projections of 21st century warming (Chapter 4, Section 4.5.1). While uncertainty in both global and tropical warming under greenhouse gas forcing is dominated by cloud feedbacks (Vial et al., 2013; Section 7.5.7), uncertainty in polar warming arises from polar surface-albedo, lapse-rate, and cloud feedbacks, changes in atmospheric and oceanic poleward heat transport, and ocean heat uptake (Hwang et al., 2011; Mahlstein and Knutti, 2011; Pithan and Mauritsen, 2014; Bonan et al., 2018).

The magnitude of polar amplification also depends on the type of radiative forcing applied (Stjern et al., 2019; Chapter 4, Section 4.5.1.1), with Chapter 6, Section 6.4.3 discussing changes in sulphate aerosol emissions and the deposition of black carbon aerosols on ice and snow as potential drivers of amplified Arctic warming. The timing of the emergence of SH polar amplification remains uncertain due to insufficient knowledge of the timescales associated with Southern Ocean warming and the response to surface wind and freshwater forcing (Bintanja et al., 2013; Kostov et al., 2017, 2018; Pauling et al., 2017; Purich et al., 2018). ESM simulations indicate that freshwater input from melting ice shelves could reduce Southern Ocean warming by up to several tenths of a °C over the 21st century by increasing stratification of the surface ocean around Antarctica (Bronselaer et al., 2018; Golledge et al., 2019; Lago and England, 2019; Section 7.4.2.6; Chapter 9, Section 9.2.1 and Box 9.3) (*low confidence* due to *medium agreement* but *limited evidence*). However, even a large reduction in the Atlantic meridional overturning circulation (AMOC) and associated northward heat transport due, for instance, to greatly increased freshwater runoff from Greenland would be insufficient to eliminate Arctic amplification (Liu et al., 2017a, 2017b; Wen et al., 2018) (*medium confidence* based on to *medium agreement* and *medium evidence*).

Arctic amplification has a distinct seasonality with a peak in early winter (Nov–Jan) owing to sea-ice loss and associated increases in heat fluxes from the ocean to the atmosphere resulting in strong near-surface warming (Pithan and Mauritsen, 2014; Dai et al., 2019). Surface warming may be further amplified by positive cloud and lapse-rate feedbacks in autumn and winter (Burt et al., 2016; Morrison et al., 2018; Hahn et al., 2020). Arctic amplification is weak in summer owing to surface temperatures remaining stable as excess energy goes into thinning the summertime sea-ice cover, which remains at the melting point, or into the ocean mixed layer. Arctic amplification can also be interpreted through changes in the surface energy budget (Burt et al., 2016; Woods and Caballero, 2016; Boeke and Taylor, 2018; Kim et al., 2019), however such analyses are complicated by the finding that a large portion of the changes in downward longwave radiation can be attributed to the lower troposphere warming along with the surface itself (Vargas Zeppetello et al., 2019).

7.4.4.1.2 Polar amplification from proxies and models during past climates associated with CO_2 change

Paleoclimate proxy data provide observational evidence of large-scale patterns of surface warming in response to past forcings, and allow an evaluation of the modelled response to these forcings (Chapter 3, Section 3.3.1.1; Section 3.8.2.1). In particular, paleoclimate data provide evidence for long-term changes in polar amplification during time periods in which the primary forcing was a change in atmospheric CO_2, although data sparsity means that for some time periods this evidence may be limited to a single hemisphere or ocean basin, or the evidence may come primarily from the mid-latitudes as opposed to the polar regions. In this context, there has been a modelling and data focus on the Last Glacial Maximum (LGM) in the context of PMIP4 (Cleator et al., 2020; Tierney et al., 2020b; Kageyama et al., 2021), the mid-Pliocene warm period (MPWP) in the context of PlioMIP2 (Chapter 2, Cross-Chapter Box 2.4; Salzmann et al., 2013; Haywood et al., 2020; McClymont et al., 2020), the early Eocene climatic optimum (EECO) in the context of DeepMIP (Hollis et al., 2019; Lunt et al., 2021), and there is growing interest in the Miocene (Goldner et al., 2014b; Steinthorsdottir et al., 2020) (for definitions of time periods see Chapter 2, Cross-Chapter Box 2.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

For all these time periods, in addition to the CO_2 forcing there are long-term feedbacks associated with ice sheets (Section 7.4.2.6), and in particular for the early Eocene there is a forcing associated with paleogeographic change (Farnsworth et al., 2019). However, because these non-CO_2 effects can all be included as boundary conditions in model simulations, these time periods allow an assessment of the patterns of modelled response to known forcing (although uncertainty in the forcing increases further back in time). Because these changes to boundary conditions can be complex to implement in models, and because long simulations (typically >500 years) are required to approach equilibrium, these simulations have been carried out mostly by pre-CMIP6 models, with relatively few (or none for the early Eocene) fully coupled CMIP6 models in the ensembles.

At the time of AR5, polar amplification was evident in proxy reconstructions of paleoclimate SST and SAT from the LGM, MPWP and the early Eocene, but uncertainties associated with proxy calibrations (Waelbroeck et al., 2009; Dowsett et al., 2012; Lunt et al., 2012a) and the role of orbital forcing (for the MPWP; Lisiecki and Raymo, 2005) meant that the degree of polar amplification during these time periods was not accurately known. Furthermore, although some models (CCSM3; Winguth et al., 2010; Huber and Caballero, 2011) at that time were able to reproduce the strong polar amplification implied by temperature proxies of the early Eocene, this was achieved at higher CO_2 concentrations (>2000 ppm) than those indicated by CO_2 proxies (<1500 ppm; Beerling and Royer, 2011).

Since AR5 there has been progress in improving the accuracy of proxy temperature reconstructions of the LGM (Cleator et al., 2020; Tierney et al., 2020b), the MPWP (McClymont et al., 2020), and the early Eocene (Hollis et al., 2019) time periods. In addition, reconstructions of the MPWP have been focused on a short time slice with an orbit similar to modern-day (isotopic stage KM5C; Haywood et al., 2013, 2016b). Furthermore, there are more robust constraints on CO_2 concentrations from the MPWP (Martínez-Botí et al., 2015; de la Vega et al., 2020) and the early Eocene (Anagnostou et al., 2016, 2020). As such, polar amplification during the LGM, MPWP, and early Eocene time periods can now be better quantified than at the time of AR5, and the ability of climate models to reproduce this pattern can be better assessed; model-data comparisons for SAT and SST for these three time periods are shown in Figure 7.13.

[START FIGURE 7.13 HERE]

Figure 7.13: Polar amplification in paleo proxies and models of the early Eocene climatic optimum (EECO), the mid-Pliocene warm period (MPWP), and the Last Glacial Maximum (LGM). Temperature anomalies compared with pre-industrial (equivalent to CMIP6 simulation *piControl*) are shown for the high-CO_2 EECO and MPWP time periods, and for the low-CO_2 LGM (expressed as pre-industrial minus LGM). (a,b,c) Modelled near-surface air temperature anomalies for ensemble-mean simulations of the (a) EECO (Lunt et al., 2021), (b) MPWP (Haywood et al., 2020; Zhang et al., 2021), and (c) LGM (Kageyama et al., 2021; Zhu et al., 2021). Also shown are proxy near-surface air temperature anomalies (coloured circles). (d,e,f) Proxy near-surface air temperature anomalies (grey circles), including published uncertainties (grey vertical bars), model ensemble mean zonal mean anomaly (solid red line) for the same model ensembles as in (a,b,c), light red lines show the modelled temperature anomaly for the individual models that make up each ensemble (LGM, N=9; MPWP, N=17; EECO, N=5). Black dashed lines show the average of the proxy values in each latitude bands 90°S to 30°S, 30°S to 30°N, and 30°N to 90°N. Red dashed lines show the same banded average in the model ensemble mean, calculated from the same locations as the proxies. Black and red dashed lines are only shown if there are 5 or more proxy points in that band. Mean differences between the 90°S/N to 30°S/N and 30°S to 30°N bands are quantified for the models and proxies in each plot. Panels (g,h,i) are like panels (d,e,f) but for SST instead of near-surface air temperature. Panels (j,k,l) are like panels (a,b,c) but for SST instead of near-surface air temperature. For the EECO maps (a,j), the anomalies are relative to the zonal mean of the pre-industrial, due to the different continental configuration. Proxy datasets are (a,d) Hollis et al. (2019), (b,e) Salzmann et al. (2013); Vieira et al. (2018), (c,f) Cleator et al. (2020) at the sites defined in Bartlein et al. (2011), (g,j)) Hollis et al. (2019), (h,k) McClymont et al. (2020) (i,l) Tierney et al. (2020b). Where there are multiple proxy estimations at a single site, a mean is taken. Model ensembles are (a,d,g,j) DeepMIP (only model simulations carried out with a mantle-frame paleogeography, and carried out under CO_2 concentrations within the range assessed in Chapter 2, Table 2.2, are shown), (b,e,h,k) PlioMIP, and (c,f,i,l) PMIP4. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[END FIGURE 7.13 HERE]

Since AR5, there has been progress in the simulation of polar amplification by paleoclimate models of the early Eocene. Initial work indicated that changes to model parameters associated with aerosols and/or clouds could increase simulated polar amplification and improve agreement between models and paleoclimate data (Kiehl and Shields, 2013; Sagoo et al., 2013), but such parameter changes were not physically based. In support of these initial findings, a more recent (CMIP5) climate model, that includes a process-based representation of cloud microphysics, exhibits polar amplification in better agreement with proxies when compared to the models assessed in AR5 (Zhu et al., 2019b). Since then, some other CMIP3 and CMIP5 models in the DeepMIP multi-model ensemble (Lunt et al., 2021) have obtained polar amplification for the EECO that is consistent with proxy indications of both polar amplification and CO_2. Although there is a lack of tropical proxy SAT estimates, both proxies and DeepMIP models show greater terrestrial warming in the high latitudes than the mid-latitudes in both Hemispheres (Figure 7.13a,d). SST proxies also exhibit polar amplification in both Hemispheres, but the magnitude of this polar amplification is too low in the models, in particular in the southwest Pacific (Figure 7.13g,j).

For the MPWP, model simulations are now in better agreement with proxies than at the time of AR5 (Haywood et al., 2020; McClymont et al., 2020). In particular, in the tropics new proxy reconstructions of SSTs are warmer and in better agreement with the models, due in part to the narrower time window in the proxy reconstructions. There is also better agreement at higher latitudes (primarily in the North Atlantic), due in part to the absence of some very warm proxy SSTs due to the narrower time window (McClymont et al., 2020), and in part to a modified representation of Arctic gateways in the most recent Pliocene model simulations (Otto-Bliesner et al., 2017), which have resulted in warmer modelled SSTs in the North Atlantic (Haywood et al., 2020). Furthermore, as for the Eocene, improvements in the representation of aerosol-cloud interactions has also led to improved model-data consistency at high latitudes (Feng et al., 2019). Although all PlioMIP2 models exhibit polar amplification of SAT, due to the relatively narrow time window there are insufficient terrestrial proxies to assess this (Figure 7.13b,e). However, polar SST amplification in the PlioMIP2 ensemble mean is in reasonably good agreement with that from SST proxies in the Northern Hemisphere (Figure 7.13h,k).

The Last Glacial Maximum (LGM) also gives an opportunity to evaluate model simulation of polar amplification under CO_2 forcing, albeit under colder conditions than today (Kageyama et al., 2021). Terrestrial SAT and marine SST proxies exhibit clear polar amplification in the Northern Hemisphere, and the PMIP4 models capture this well (Figure 7.13c,f,i,l), in particular for SAT. There is less proxy data in the mid to high latitudes of the Southern Hemisphere, but here the models exhibit polar amplification of both SST and SAT. LGM regional model-data agreement is also assessed in Chapter 3, Section 3.8.2.

Overall, the proxy reconstructions give *high confidence* that there was polar amplification in the LGM, MPWP and EECO, and this is further supported by model simulations of these time periods (Zhu et al., 2019b; Haywood et al., 2020; Kageyama et al., 2021; Lunt et al., 2021; Figure 7.13). For both the MPWP and EECO, models are more consistent with the temperature and CO_2 proxies than at the time of AR5 (*high confidence*). For the LGM Northern Hemisphere, which is the region with the most data and the time period with the least uncertainty in model boundary conditions, polar amplification in the PMIP4 ensemble mean is in good agreement with the proxies, especially for SAT (*medium confidence*). Overall, the confidence in the ability of models to accurately simulate polar amplification is higher than at the time of AR5, but a more complete model evaluation could be carried out if there were more CMIP6 paleoclimate simulations included in the assessment.

7.4.4.1.3 Overall assessment of polar amplification

Based on mature process understanding of the roles of poleward latent heat transport and radiative feedbacks in polar warming, a high degree of agreement across a hierarchy of climate models, observational evidence, paleoclimate proxy records of past climates associated with CO_2 change, and ESM simulations of those past

ACCEPTED VERSION SUBJECT TO FINAL EDITING

climates, there is *high confidence* that polar amplification is a robust feature of the long-term response to greenhouse gas forcing in both hemispheres. Stronger warming in the Arctic than in the global average has already been observed (Chapter 2, Section 2.3.1) and its causes are well understood. It is *very likely* that the warming in the Arctic will be more pronounced than on global average over the 21st century (*high confidence*) (Chapter 4, Section 4.5.1.1). This is supported by models' improved ability to simulate polar amplification during past time periods, compared with at the time of AR5 (*high confidence*); although this is based on an assessment of mostly non-CMIP6 models.

Southern Ocean SSTs have been slow to warm over the instrumental period, with cooling since about 1980 owing to a combination of upper-ocean freshening from ice-shelf melt, intensification of surface westerly winds from ozone depletion, and variability in ocean convection (Chapter 9, Section 9.2.1). This stands in contrast to the equilibrium warming pattern either inferred from the proxy record or simulated by ESMs under CO_2 forcing. There is *high confidence* that the SH high latitudes will warm more than the tropics on centennial timescales as the climate equilibrates with radiative forcing and Southern Ocean heat uptake is reduced. However, there is only *low confidence* that this feature will emerge this century.

7.4.4.2 Tropical Pacific sea-surface temperature gradients

Research published since AR5 identifies changes in the tropical Pacific Ocean zonal SST gradient over time as a key factor affecting how radiative feedbacks may evolve in the future (Section 7.4.4.3). There is now a much-improved understanding of the processes that govern the tropical Pacific SST gradient (Section 7.4.4.2.1) and the paleoclimate record provides evidence for its equilibrium changes from time periods associated with changes in CO_2 (Section 7.4.4.2.2).

7.4.4.2.1 Critical processes determining changes in tropical Pacific sea-surface temperature gradients

A weakening of the equatorial Pacific Ocean east-west SST gradient, with greater warming in the East than the west, is a common feature of the climate response to greenhouse gas forcing as projected by ESMs on centennial and longer timescales (e.g., Figure 7.14b) (Chapter 4, Section 4.5.1). There are thought to be several factors contributing to this pattern. In the absence of any changes in atmospheric or oceanic circulations, the east-west surface temperature difference is theorized to decrease owing to weaker evaporative damping, and thus greater warming in response to forcing, where climatological temperatures are lower in the eastern Pacific cold tongue (Xie et al., 2010; Luo et al., 2015). Within atmospheric ESMs coupled to mixed-layer ocean, this gradient in damping has been linked to the rate of change with warming of the saturation specific humidity, which is set by the Clausius-Clapeyron relation (Merlis and Schneider, 2011). Gradients in low-cloud feedbacks may also favour eastern equatorial Pacific warming (DiNezio et al., 2009).

In the coupled climate system, changes in atmospheric and oceanic circulations will influence the east-west temperature gradient as well. It is expected that as global temperature increases and as the east-west temperature gradient weakens, east-west sea-level pressure gradients and easterly trade winds (characterizing the Walker circulation) will weaken as well (Vecchi et al., 2006, 2008; Figure 7.14b; Chapter 8, Sections 8.2.2.2 and 8.4.2.3; Chapter 4, Section 4.5.3). This would, in turn, weaken the east-west temperature gradient through a reduction of equatorial upwelling of cold water in the east Pacific and a reduction in the transport of warmer water to the western equatorial Pacific and Indian Ocean (England et al., 2014; Dong and McPhaden, 2017; Li et al., 2017; Maher et al., 2018).

Research published since AR5 (Burls and Fedorov, 2014a; Fedorov et al., 2015; Erfani and Burls, 2019) has built on an earlier theory (Liu and Huang, 1997; Barreiro and Philander, 2008) linking the east-west temperature gradient to the north-south temperature gradient. In particular, model simulations suggest that a reduction in the equator-to-pole temperature gradient (polar amplification) increases the temperature of water subducted in the extra-tropics, which in turn is upwelled in the eastern Pacific. Thus, polar amplified warming, with greater warming in the mid-latitudes and subtropics than in the deep tropics, is expected to contribute to the weakening of the east-west equatorial Pacific SST gradient on decadal to centennial

ACCEPTED VERSION SUBJECT TO FINAL EDITING

timescales.

The transient adjustment of the equatorial Pacific SST gradient is influenced by upwelling waters which delay surface warming in the east since they have not been at the surface for years-to-decades to experience the greenhouse gas forcing. This 'thermostat mechanism' (Clement et al., 1996; Cane et al., 1997) is not thought to persist to equilibrium since it does not account for the eventual increase in temperatures of upwelled waters (Liu et al., 2005; Xie et al., 2010; Luo et al., 2017b) which will occur as the subducting waters in mid-latitudes warm by more than the tropics on average as polar amplification emerges. An individual CMIP5 ESM (GFDL's ESM2M) has been found to exhibit a La Niña–like pattern of Pacific temperature change through the 21st century, similar to the SST trends seen over the historical record (Chapter 9, Section 9.2.1; Figure 7.14a), owing to a weakening asymmetry between El Niño and La Niña events (Kohyama et al., 2017), but this pattern of warming may not persist to equilibrium (Paynter et al., 2018).

Since 1870, observed SSTs in the tropical western Pacific Ocean have increased while those in the tropical eastern Pacific Ocean have changed less (Figure 7.14a; Chapter 9, Section 9.2.1). Much of the resultant strengthening of the equatorial Pacific temperature gradient has occurred since about 1980 due to strong warming in the west and cooling in the east (Chapter 2, Figure 2.11b) concurrent with an intensification of the surface equatorial easterly trade winds and Walker Circulation (England et al., 2014; Chapter 3, Section 3.3.3.1, Section 3.7.6, Figure 3.16f, Figure 3.39f; Chapter 8, Section 8.3.2.3; Chapter 9, Section 9.2). This temperature pattern is also reflected in regional ocean heat content trends and sea level changes observed from satellite altimetry since 1993 (Bilbao et al., 2015; Richter et al., 2020). The observed changes may have been influenced by one or a combination of temporary factors including sulphate aerosol forcing (Smith et al., 2016; Takahashi and Watanabe, 2016; Hua et al., 2018), internal variability within the Indo-Pacific Ocean (Luo et al., 2012; Chung et al., 2019), teleconnections from multi-decadal tropical Atlantic SST trends (Kucharski et al., 2011, 2014, 2015; McGregor et al., 2014; Chafik et al., 2016; Li et al., 2016a; Kajtar et al., 2017; Sun et al., 2017), teleconnections from multi-decadal Southern Ocean SST trends (Hwang et al., 2017), and coupled ocean–atmosphere dynamics which slow warming in the equatorial eastern Pacific (Clement et al., 1996; Cane et al., 1997; Seager et al., 2019). CMIP3 and CMIP5 ESMs have difficulties replicating the observed trends in the Walker Circulation and Pacific Ocean SSTs over the historical record (Sohn et al., 2013; Zhou et al., 2016; Coats and Karnauskas, 2017), possibly due to model deficiencies including insufficient multi-decadal Pacific Ocean SST variability (Laepple and Huybers, 2014; Bilbao et al., 2015; Chung et al., 2019), mean state biases affecting the forced response or the connection between Atlantic and Pacific basins (Kucharski et al., 2014; Kajtar et al., 2018; Luo et al., 2018; McGregor et al., 2018; Seager et al., 2019), and/or a misrepresentation of radiative forcing (Chapter 9, Section 9.2.1 and Chapter 3, Section 3.7.6). However, the observed trends in the Pacific Ocean SSTs are still within the range of internal variability as simulated by large initial condition ensembles of CMIP5 and CMIP6 models (Olonscheck et al., 2020; Watanabe et al., 2020a). Because the causes of observed equatorial Pacific temperature gradient and Walker circulation trends are not well understood (Chapter 3, Section 3.3.3.1), there is *low confidence* in their attribution to anthropogenic influences (Chapter 8, Section 8.3.2.3), while there is *medium confidence* that the observed changes have resulted from internal variability (Chapter 8, Section 8.2.2.2; Chapter 3, Section 3.7.6).

7.4.4.2.2 Tropical Pacific temperature gradients in past high-CO_2 climates

AR5 stated that paleoclimate proxies indicate a reduction in the longitudinal SST gradient across the equatorial Pacific during the mid-Pliocene warm period (MPWP; Cross-Chapter Box 2.1; Cross-Chapter Box 2.4; Masson-Delmotte et al., 2013). This assessment was based on SST reconstructions between two sites situated very close to the equator in the heart of the western Pacific warm pool and eastern Pacific cold tongue, respectively. Multiple SST reconstructions based on independent paleoclimate proxies generally agreed that during the Pliocene the SST gradient between these two sites was reduced compared with the modern long-term mean (Wara et al., 2005; Dekens et al., 2008; Fedorov et al., 2013).

Since AR5, the generation of new SST records has led to a variety of revised gradient estimates, specifically the generation of a new record for the warm pool (Zhang et al., 2014), the inclusion of SST reconstructions

ACCEPTED VERSION SUBJECT TO FINAL EDITING

from sites in the South China Sea as warm pool estimates (O'Brien et al., 2014; Zhang et al., 2014), and the inclusion of several new sites from the eastern Pacific as cold tongue estimates (Zhang et al., 2014; Fedorov et al., 2015). Published estimates of the reduction in the longitudinal SST difference for the Late Pliocene, relative to either Late Quaternary (0-0.5Ma) or pre-industrial values, include 1 to 1.5°C (Zhang et al., 2014), 0.1 to 1.9°C (Tierney et al., 2019), and about 3°C (Ravelo et al., 2014; Fedorov et al., 2015; Wycech et al., 2020). All of these studies report a further weakening of the longitudinal gradient based on records extending into the Early Pliocene. While these revised estimates differ in magnitude due to differences in the sites and SST proxies used, they all agree that the longitudinal gradient was weaker, and this is supported by the probabilistic approach of Tierney et al. (2019). However, given that there are currently relatively few western equatorial Pacific records from independent site locations, and due to uncertainties associated with the proxy calibrations (Haywood et al., 2016a), there is only *medium confidence* that the average longitudinal gradient in the tropical Pacific was weaker during the Pliocene than during the Late Quaternary.

To avoid the influence of local biases, changes in the longitudinal temperature difference within Pliocene model simulations are typically evaluated using domain-averaged SSTs within chosen east and west Pacific regions and as such there is sensitivity to methodology. Unlike the reconstructed estimates, longitudinal gradient changes simulated by the Pliocene Model Intercomparison Project Phase 1 (PlioMIP1) models do not agree on the change in sign and are reported as spanning approximately –0.5 to 0.5 °C by Brierley et al. (2015) and approximately –1 to 1 °C by Tierney et al. (2019). Initial PlioMIP Phase 2 (PlioMIP2) analysis suggests responses similar to PlioMIP1 (Feng et al., 2019; Haywood et al., 2020). Models that include hypothetical modifications to cloud albedo or ocean mixing are required to simulate the substantially weaker longitudinal differences seen in reconstructions of the early Pliocene (Fedorov et al., 2013; Burls and Fedorov, 2014b).

While more western Pacific warm pool temperature reconstructions are needed to refine estimates of the longitudinal gradient, several Pliocene SST reconstructions from the east Pacific indicate enhanced warming in the centre of the eastern equatorial cold tongue upwelling region (Liu et al., 2019). This enhanced warming in the east Pacific cold tongue appears to be dynamically consistent with reconstruction of enhanced subsurface warming (Ford et al., 2015) and enhanced warming in coastal upwelling regions, suggesting that the tropical thermocline was deeper and/or less stratified during the Pliocene. The Pliocene data therefore suggests that the observed cooling trend over the last 60 years in parts of the eastern equatorial Pacific (Seager et al., 2019; Chapter 9, Section 9.2.1.1; Figure 9.3), whether forced or due to internal variability, involves transient processes that are probably distinct from the longer-timescale process (Burls and Fedorov, 2014a, 2014b; Luo et al., 2015; Heede et al., 2020) that maintained warmer eastern Pacific SST during the Pliocene.

7.4.4.2.3 Overall assessment of tropical Pacific sea-surface temperature gradients under CO_2 forcing

The paleoclimate proxy record and ESM simulations of the MPWP, process understanding, and ESM projections of climate response to CO_2 forcing provide medium evidence and a medium degree of agreement and thus *medium confidence* that equilibrium warming in response to elevated CO_2 will be characterized by a weakening of the east-west tropical Pacific SST gradient.

Overall the observed pattern of warming over the instrumental period, with a warming minimum in the eastern tropical Pacific Ocean (Figure 7.14a), stands in contrast to the equilibrium warming pattern either inferred from the MPWP proxy record or simulated by ESMs under CO_2 forcing. There is *medium confidence* that the observed strengthening of the east-west SST gradient is temporary and will transition to a weakening of the SST gradient on centennial timescales. However, there is only *low confidence* that this transition will emerge this century owing to a low degree of agreement across studies about the factors driving the observed strengthening of the east-west SST gradient and how those factors will evolve in the future. These trends in tropical Pacific SST gradients reflect changes in the climatology, rather than changes in ENSO amplitude or variability, which are assessed in Chapter 4, Section 4.3.3.

7.4.4.3 Dependence of feedbacks on temperature patterns

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The expected time-evolution of the spatial pattern of surface warming in the future has important implications for values of ECS inferred from the historical record of observed warming. In particular, changes in the global TOA radiative energy budget can be induced by changes in the regional variations of surface temperature, even without a change in the global mean temperature (Zhou et al., 2016; Ceppi and Gregory, 2019). Consequently, the global radiative feedback, characterizing the net TOA radiative response to global surface warming, depends on the *spatial pattern* of that warming. Therefore, if the equilibrium warming pattern under CO_2 forcing (similar to CMIP6 projections in Fig. 7.12a) is distinct from that observed over the historical record or indicated by paleoclimate proxies (Sections 7.4.4.1 and 7.4.4.2), then ECS will be different from the effective ECS (Box 7.1) that is inferred from those periods. Accounting for the dependence of radiative feedbacks on the spatial pattern of warming has helped to reconcile values of ECS inferred from the historical record with values of ECS based on other lines of evidence and simulated by climate models (Armour, 2017; Proistosescu and Huybers, 2017; Andrews et al., 2018; Section 7.5.2.1) but has not yet been examined in the paleoclimate context.

This temperature "pattern effect" (Stevens et al., 2016) can result from both internal variability and radiative forcing of the climate system. Importantly, it is distinct from potential radiative feedback dependencies on the global surface temperature, which are assessed in Section 7.4.3. While changes in global radiative feedbacks under transient warming have been documented in multiple generations of climate models (Williams et al., 2008; Andrews et al., 2015; Ceppi and Gregory, 2017; Dong et al., 2020), research published since AR5 has developed a much-improved understanding of the role of evolving SST patterns in driving feedback changes (Armour et al., 2013; Andrews et al., 2015, 2018, Zhou et al., 2016, 2017b; Gregory and Andrews, 2016; Proistosescu and Huybers, 2017; Ceppi and Gregory, 2017; Haugstad et al., 2017; Andrews and Webb, 2018; Silvers et al., 2018; Marvel et al., 2018; Dong et al., 2019, 2020). This section assesses process understanding of the pattern effect, which is dominated by the evolution of SSTs. Section 7.5.2.1 describes how potential feedback changes associated with the pattern effect are important to interpreting ECS estimates based on historical warming.

The radiation changes most sensitive to warming patterns are those associated with the low-cloud cover (affecting global albedo) and the tropospheric temperature profile (affecting thermal emission to space) (Ceppi and Gregory, 2017; Zhou et al., 2017b; Andrews et al., 2018; Dong et al., 2019). The mechanisms and radiative effects of these changes are illustrated in Figure 7.14a,b. SSTs in regions of deep convective ascent (e.g., in the western Pacific warm pool) govern the temperature of the tropical free troposphere and, in turn, affect low clouds through the strength of the inversion that caps the boundary layer (i.e., the lower-tropospheric stability) in subsidence regions (Wood and Bretherton, 2006; Klein et al., 2017). Surface warming within ascent regions thus warms the free troposphere and increases low-cloud cover, causing an increase in emission of thermal radiation to space and a reduction in absorbed solar radiation. In contrast, surface warming in regions of overall descent preferentially warms the boundary layer and enhances convective mixing with the dry free troposphere, decreasing low-cloud cover (Bretherton et al., 2013; Qu et al., 2014; Zhou et al., 2015). This leads to an increase in absorption of solar radiation but little change in thermal emission to space. Consequently, warming in tropical ascent regions results in negative lapse-rate and cloud feedbacks while warming in tropical descent regions results in positive lapse-rate and cloud feedbacks (Figure 7.14; Rose and Rayborn, 2016; Zhou et al., 2017b; Andrews and Webb, 2018; Dong et al., 2019). Surface warming in mid-to-high latitudes causes a weak radiative response owing to compensating changes in thermal emission (Planck and lapse-rate feedbacks) and absorbed solar radiation (shortwave cloud and surface-albedo feedbacks) (Rose and Rayborn, 2016; Dong et al., 2019), however this compensation may weaken due to less-negative shortwave cloud feedbacks at high warming (Frey and Kay, 2018; Bjordal et al., 2020; Dong et al., 2020).

[START FIGURE 7.14 HERE]

Figure 7.14: Illustration of tropospheric temperature and low-cloud response to observed and projected Pacific Ocean sea-surface temperature trends; adapted from Mauritsen (2016). (a) Atmospheric response to linear sea-surface temperature trend observed over 1870–2019 (HadISST1 dataset; Rayner et al., 2003).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(b) Atmospheric response to linear sea-surface temperature trend over 150 years following *abrupt4xCO2* forcing as projected by CMIP6 ESMs (Dong et al., 2020). Relatively large historical warming in the western tropical Pacific has been communicated aloft (a shift from grey to red atmospheric temperature profile), remotely warming the tropical free troposphere and increasing the strength of the inversion in regions of the tropics where warming has been slower, such as the eastern equatorial Pacific. In turn, an increased inversion strength has increased the low-cloud cover (Zhou et al., 2016) causing an anomalously-negative cloud and lapse-rate feedbacks over the historical record (Andrews et al., 2018; Marvel et al., 2018). Relatively large projected warming in the eastern tropical Pacific is trapped near the surface (shift from grey to red atmospheric temperature profile), decreasing the strength of the inversion locally. In turn, a decreased inversion strength combined with surface warming is projected to decrease the low-cloud cover, causing the cloud and lapse-rate feedbacks to become less negative in the future. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.14 HERE]

The spatial pattern of SST changes since 1870 shows relatively little warming in key regions of less-negative radiative feedbacks, including the eastern tropical Pacific Ocean and Southern Ocean (Sections 7.4.4.1 and 7.4.4.2; Figure 7.14a; Chapter 2, Figure 2.11b). Cooling in these regions since 1980 has occurred along with an increase in the strength of the capping inversion in tropical descent regions, resulting in an observed increase in low-cloud cover over the tropical eastern Pacific (Zhou et al., 2016; Ceppi and Gregory, 2017; Fueglistaler and Silvers, 2021; Figure 7.14a). Thus, tropical low-cloud cover increased over recent decades even as global surface temperature increased, resulting in a negative low-cloud feedback which is at odds with the positive low-cloud feedback expected for the pattern of equilibrium warming under CO_2 forcing (Section 7.4.2.4; Figure 7.14b).

Andrews et al. (2018) analysed available CMIP5/6 ESM simulations (six in total) comparing effective feedback parameters diagnosed within atmosphere-only ESMs using prescribed historical SST and sea-ice concentration patterns with the equilibrium feedback parameters as estimated within coupled ESMs (using identical atmospheres) driven by abrupt 4×CO_2 forcing. The atmosphere-only ESMs show pronounced multi-decadal variations in their effective feedback parameters over the last century, with a trend toward strongly negative values since about 1980 owing primarily to negative shortwave cloud feedbacks driven by warming in the western equatorial Pacific Ocean and cooling in the eastern equatorial Pacific Ocean (Zhou et al., 2016; Andrews et al., 2018; Marvel et al., 2018; Dong et al., 2019). Yet, all six models show a less-negative net feedback parameter under *abrupt4xCO2* than for the historical period (based on regression since 1870 following Andrews et al., 2018). The average change in net feedback parameter between the historical period and the equilibrium response to CO_2 forcing, denoted here as α', for these simulations is α' = +0.6 W m^{-2} °C^{-1} (+0.3 to +1.0 W m^{-2} °C^{-1} range across models) (Figure 7.15b). These feedback parameter changes imply that the value of ECS may be substantially larger than that inferred from the historical record (Section 7.5.2.1). These findings can be understood from the fact that, due to a combination of internal variability and transient response to forcing (Section 7.4.4.2), historical sea-surface warming has been relatively large in regions of tropical ascent (Figure 7.14a), leading to an anomalously large net negative radiative feedback; however, future warming is expected to be largest in tropical descent regions, such as the eastern equatorial Pacific, and at high latitudes (Sections 7.4.4.1 and 7.4.4.2; Figure 7.14b), leading to a less-negative net radiative feedback and higher ECS.

A similar behaviour is seen within transient simulations of coupled ESMs, which project SST warming patterns that are initially characterised by relatively large warming rates in the western equatorial Pacific Ocean on decadal timescales and relatively large warming in the eastern equatorial Pacific and Southern Ocean on centennial timescales (Andrews et al., 2015; Proistosescu and Huybers, 2017; Dong et al., 2020). Recent studies based on simulations of 1% yr^{-1} CO_2 increase (*1pctCO2*) or *abrupt4xCO2* as analogues for historical warming suggest characteristic values of α' = +0.05 W m^{-2} °C^{-1} (–0.2 to +0.3 W m^{-2} °C^{-1} range across models) based on CMIP5 and CMIP6 ESMs (Armour 2017, Lewis and Curry 2018, Dong et al. 2020). Using historical simulations of one CMIP6 ESM (HadGEM3-GC3.1-LL), Andrews et al., (2019) find an average feedback parameter change of α' = +0.2 W m^{-2} °C^{-1}(–0.2 to +0.6 W m^{-2} °C^{-1} range across four ensemble members). Using historical simulations from another CMIP6 ESM (GFDL CM4.0), Winton et al.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(2020) find an average feedback parameter change of α' = +1.5 W m^{-2} °C^{-1}(+1.2 to +1.7 W m^{-2} °C^{-1} range across three ensemble members). This value is larger than the α' = +0.7 W m^{-2} °C^{-1} within GFDL CM4.0 for historical CO_2 forcing only, suggesting that the value of α' may depend on historical non-CO_2 forcings such as those associated with tropospheric and stratospheric aerosols (Marvel et al., 2016; Gregory et al., 2020; Winton et al., 2020).

The magnitude of the net feedback parameter change α' found within coupled CMIP5 and CMIP6 ESMs is generally smaller than that found when prescribing observed warming patterns within atmosphere-only ESMs (Andrews et al., 2018; Figure 7.15). This arises from the fact that the forced spatial pattern of warming within transient simulations of most coupled ESMs are distinct from observed warming patterns over the historical record in key regions such as the equatorial Pacific Ocean and Southern Ocean (Sections 7.4.4.1 and 7.4.4.2), while being more similar to the equilibrium pattern simulated under *abrupt4xCO2*. However, historical simulations with HadGEM3-GC3.1-LL (Andrews et al., 2019) and GFDL CM4.0 (Winton et al., 2020) show substantial spread in the value of α' across ensemble members, indicating a potentially important role for internal variability in setting the magnitude of the pattern effect over the historical period. Using the 100-member historical simulation ensemble of MPI- ESM1.1, Dessler et al. (2018) find that internal climate variability alone results in a 0.5 W m^{-2} °C^{-1} spread in the historical effective feedback parameter, and thus also in the value of α'. Estimates of α' using prescribed historical warming patterns provide a more realistic representation of the historical pattern effect because they account for the net effect of the transient response to historical forcing and internal variability in the observed record (Andrews et al., 2018).

The magnitude of α', as quantified by ESMs, depends on the accuracy of both the projected patterns of SST and sea-ice concentration changes in response to CO_2 forcing and the radiative response to those patterns (Andrews et al., 2018). Model biases that affect the long-term warming pattern (e.g., SST and relative humidity biases in the equatorial Pacific cold tongue as suggested by Seager et al. (2019)) will affect the value of α'. The value of α' also depends on the accuracy of the historical SST and sea-ice concentration conditions prescribed within atmosphere-only versions of ESMs to quantify the historical radiative feedback (Figure 7.15b). Historical SSTs are particularly uncertain for the early portion of the historical record (Chapter 2, Section 2.3.1), and there are few constraints on sea-ice concentration prior to the satellite era. Using alternative SST datasets, Andrews et al. (2018) found little change in the value of α' within two models (HadGEM3 and HadAM3), while Lewis and Mauritsen (2020) found a smaller value of α' within two other models (ECHAM6.3 and CAM5). The sensitivity of results to the choice of dataset represents a major source of uncertainty in the quantification of the historical pattern effect using atmosphere-only ESMs that has yet to be systematically explored, but the preliminary findings of Lewis and Mauritsen (2020) and Fueglistaler and Silvers (2021) suggest that α' could be smaller than the values reported in Andrews et al. (2018).

[START FIGURE 7.15 HERE]

Figure 7.15: Relationship between *historical* and *abrupt4xCO2* net radiative feedbacks in ESMs. (a) Radiative feedbacks in CMIP6 ESMs estimated under historical forcing (values for GFDL CM4.0 and HadGEM3-CG3.1-LL from Winton et al. (2020) and Andrews et al. (2019), respectively); horizontal lines show the range across ensemble members. The other points show effective feedback values for 29 ESMs estimated using regression over the first 50 years of *abrupt4xCO2* simulations as an analogue for historical warming (Dong et al., 2020). (b) Historical radiative feedbacks estimated from atmosphere-only ESMs with prescribed observed sea-surface temperature and sea-ice concentration changes (Andrews et al. 2018) based on a linear regression of global TOA radiation against global near-surface air temperature over the period 1870–2010 (pattern of warming similar to Figure 7.14a) and compared with equilibrium feedbacks in a *abrupt4xCO2* simulations of coupled versions of the same ESMs (pattern of warming similar to Figure 7.14b). In all cases, the equilibrium feedback magnitudes are estimated as CO_2 ERF divided by ECS where ECS is derived from regression over years 1–150 of *abrupt4xCO2* simulations (Box 7.1); similar results are found if the equilibrium feedback is estimated directly from the slope of the linear regression. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[END FIGURE 7.15 HERE]

While there are not yet direct observational constraints on the magnitude of the pattern effect, satellite measurements of variations in TOA radiative fluxes show strong co-variation with changing patterns of SSTs, with a strong dependence on SST changes in regions of deep convective ascent (e.g., in the western Pacific warm pool) (Loeb et al., 2018b; Fueglistaler, 2019). Cloud and TOA radiation responses to observed warming patterns in atmospheric models have been found to compare favourably with those observed by satellite (Zhou et al., 2016; Loeb et al., 2020; Section 7.2.2.1; Figure 7.3). This observational and modelling evidence indicates the potential for a strong pattern effect in nature that will only be negligible if the observed pattern of warming since pre-industrial levels persists to equilibrium – an improbable scenario given that Earth is in a relatively early phase of transient warming and that reaching equilibrium would take multiple millennia (Li et al., 2013a). Moreover, paleoclimate proxies, ESM simulations, and process understanding indicate that strong warming in the eastern equatorial Pacific Ocean (with *medium confidence*) and Southern Ocean (with *high confidence*) will emerge on centennial timescales as the response to CO_2 forcing dominates temperature changes in these regions (Sections 7.4.4.1; 7.4.4.2; Chapter 9, Section 9.2.1). However, there is *low confidence* that these features, which have been largely absent over the historical record, will emerge this century (Sections 7.4.4.1; 7.4.4.2; Chapter 9, Section 9.2.1). This leads to *high confidence* that radiative feedbacks will become less negative as the CO_2-forced pattern of surface warming emerges ($\alpha' > 0$ W m^{-2} °C^{-1}), but *low confidence* that these feedback changes will be realized this century. There is also substantial uncertainty in the magnitude of the net radiative feedback change between the present warming pattern and the projected equilibrium warming pattern in response to CO_2 forcing owing to the fact that its quantification currently relies solely on ESM results and is subject to uncertainties in historical SST patterns. Thus, based on the pattern of warming since 1870, α' is estimated to be in the range 0.0 to 1.0 W m^{-2} °C^{-1} but with a *low confidence* in the upper end of this range. A value of $\alpha' = +0.5 \pm 0.5$ W m^{-2} °C^{-1} is used to represent this range in Box 7.2 and Section 7.5.2, which respectively assess the implications of changing radiative feedbacks for Earth's energy imbalance and estimates of ECS based on the instrumental record. The value of α' is larger if quantified based on the observed pattern of warming since 1980 (Chapter 2, Figure 2.11b) which is more distinct from the equilibrium warming pattern expected under CO_2 forcing (similar to CMIP6 projections shown in Figure 7.12a) (Andrews et al., 2018) (*high confidence*).

7.5 Estimates of ECS and TCR

Equilibrium climate sensitivity (ECS) and transient climate response (TCR) are metrics of the global surface air temperature (GSAT) response to forcing, as defined in Section 7.1; Box 7.1. ECS is the magnitude of the long-term GSAT increase in response to a doubling of atmospheric CO_2 concentration after the planetary energy budget is balanced, though leaving out feedbacks associated with ice sheets; whereas the TCR is the magnitude of GSAT increase at year 70 when CO_2 concentration is doubled in a 1% yr^{-1} increase scenario. Both are idealised quantities, but can be inferred from paleoclimate or observational records or estimated directly using climate simulations, and are strongly correlated with the climate response in realistic future projections (Grose et al., 2018; Chapter 4, Section 4.3.4; Section 7.5.7).

TCR is always smaller than ECS because ocean heat uptake acts to reduce the rate of surface warming. Yet, TCR is related with ECS across CMIP5 and CMIP6 models (Grose et al., 2018; Flynn and Mauritsen, 2020) as expected since TCR and ECS are inherently measures of climate response to forcing; both depend on effective radiative forcing (ERF) and the net feedback parameter, α. The relationship between TCR and ECS is, however, non-linear and becomes more so for higher ECS values (Hansen et al., 1985; Knutti et al., 2005; Millar et al., 2015; Flynn and Mauritsen, 2020; Tsutsui, 2020) owing to ocean heat uptake processes and surface temperature pattern effects temporarily reducing the rate of surface warming. When α is small in magnitude, and correspondingly ECS is large (recall that ECS is inversely proportional to α), these temporary effects are increasingly important in reducing the ratio of TCR to ECS.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Before the AR6, the assessment of ECS relied on either CO_2-doubling experiments using global atmospheric models coupled with mixed-layer ocean or standardized CO_2-quadrupling (*abrupt4xCO2*) experiments using fully coupled ocean-atmosphere models or Earth system models (ESMs). The TCR has similarly been diagnosed from ESMs in which the CO_2 concentration is increased at 1% yr^{-1} (*1pctCO2*, an approximately linear increase in ERF over time) and is in practice estimated as the average over a 20–year period centred at the time of atmospheric CO_2 doubling, i.e., year 70. In the AR6, the assessments of ECS and TCR are made based on multiple lines of evidence, with ESMs representing only one of several sources of information. The constraints on these climate metrics are based on radiative forcing and climate feedbacks assessed from process understanding (Section 7.5.1), climate change and variability seen within the instrumental record (Section 7.5.2), paleoclimate evidence (Section 7.5.3), emergent constraints (Section 7.5.4), and a synthesis of all lines of evidence (Section 7.5.5). In AR5, these lines of evidence were not explicitly combined in the assessment of climate sensitivity, but as demonstrated by Sherwood et al.（2020) their combination narrows the uncertainty ranges of ECS compared to that assessed in AR5. ECS values found in CMIP6 models, some of which exhibit values higher than 5 °C (Meehl et al., 2020; Zelinka et al., 2020), are discussed in relation to the AR6 assessment in section 7.5.6.

7.5.1 Estimates of ECS and TCR based on process understanding

This section assesses the estimates of ECS and TCR based on process understanding of the ERF due to a doubling of CO_2 concentration and the net climate feedback (Sections 7.3.2 and 7.4.2). This process-based assessment is made in Section 7.5.1.1 and applied to TCR in Section 7.5.1.2.

7.5.1.1 ECS estimated using process-based assessments of the forcing and feedbacks

The process-based assessment is based on the global energy budget equation (Box 7.1, Equation 7.1), where the ERF (ΔF) is set equal to the effective radiative forcing due to a doubling of CO_2 concentration (denoted as $\Delta F_{2\times CO2}$) and the climate state reaches a new equilibrium, i.e., Earth's energy imbalance averages to zero ($\Delta N = 0$). ECS is calculated as the ratio between the ERF and the net feedback parameter: ECS = $-\Delta F_{2\times CO2}/\alpha$. Estimates of $\Delta F_{2\times CO2}$ and α are obtained separately based on understanding of the key processes that determine each of these quantities. Specifically, $\Delta F_{2\times CO2}$ is estimated based on instantaneous radiative forcing that can be accurately obtained using line-by-line calculations, to which uncertainty due to adjustments are added (Section 7.3.2). The range of α is derived by aggregating estimates of individual climate feedbacks based not only on ESMs but also on theory, observations, and high-resolution process modelling (Section 7.4.2).

The effective radiative forcing of CO_2 doubling is assessed to be $\Delta F_{2\times CO2} = 3.93 \pm 0.47$ W m^{-2} (Section 7.3.2.1), while the net feedback parameter is assessed to be $\alpha = -1.16 \pm 0.40$ W m^{-2} °C^{-1} (Section 7.4.2.7, Table 7.10), where the ranges indicate one standard deviation. These values are slightly different from those directly calculated from ESMs because more information is used to assess them, as explained above. Assuming $\Delta F_{2\times CO2}$ and α each follow an independent normal distribution, the uncertainty range of ECS can be obtained by substituting the respective probability density function into the expression of ECS (red curved bar in Figure 7.16). Since α is in the denominator, the normal distribution leads to a long tail in ECS toward high values, indicating the large effect of uncertainty in α in estimating the likelihood of a high ECS (Roe and Baker, 2007; Knutti and Hegerl, 2008).

The wide range of the process-based ECS estimate is not due solely to uncertainty in the estimates of $\Delta F_{2\times CO2}$ and α, but is partly explained by the assumption that $\Delta F_{2\times CO2}$ and α are independent in this approach. In CMIP5 and CMIP6 ensembles, $\Delta F_{2\times CO2}$ and α are negatively correlated when they are calculated using linear regression in *abrupt4xCO2* simulations ($r^2 = 0.34$) (Andrews et al., 2012; Webb et al., 2013; Zelinka et al., 2020). The negative correlation leads to compensation between the inter-model spreads of these quantities, thereby reducing the ECS range estimated directly from the models. If the process-based ECS distribution is reconstructed from probability distributions of $\Delta F_{2\times CO2}$ and α assuming that they are

ACCEPTED VERSION SUBJECT TO FINAL EDITING

correlated as in CMIP model ensembles, the range of ECS will be narrower by 14% (pink curved bar in Figure 7.16). If, however, the covariance between $\Delta F_{2\times CO2}$ and α is not adopted, there is no change in the mean, but the wide range still applies.

A significant correlation between $\Delta F_{2\times CO2}$ and α also occurs when the two parameters are estimated separately from AGCM fixed-SST experiments (Section 7.3.1) or fixed CO_2 concentration experiments (Ringer et al., 2014; Chung and Soden, 2018; Section 7.4.1). Hence the relationship is not expected to be an artefact of calculating them using linear regression in *abrupt4xCO2* simulations. A possible physical cause of the correlation may be a compensation between the cloud adjustment and the cloud feedback over the tropical ocean (Ringer et al., 2014; Chung and Soden, 2018). It has been shown that the change in the hydrological cycle is a controlling factor for the low-cloud adjustment (Dinh and Fueglistaler, 2019) and for the low-cloud feedback (Watanabe et al., 2018), and therefore the responses of these clouds to the direct CO_2 radiative forcing and to the surface warming may not be independent. However, robust physical mechanisms are not yet established, and furthermore, the process-based assessment of the tropical low-cloud feedback is only indirectly based on ESMs given that physical processes which control the low clouds are not sufficiently well-simulated in models (Section 7.4.2.4). For these reasons, the co-dependency between $\Delta F_{2\times CO2}$ and α is assessed to have *low confidence* and, therefore, the more conservative assumption that they are independent for the process-based assessment of ECS is retained.

In summary, the ECS based on the assessed values of $\Delta F_{2\times CO2}$ and α is assessed to have a median value of 3.4°C with a *likely* range of 2.5–5.1 °C and *very likely* range of 2.1–7.7 °C. To this assessed range of ECS, the contribution of uncertainty in α is approximately three times as large as the contribution of uncertainty in $\Delta F_{2\times CO2}$.

[START FIGURE 7.16 HERE]

Figure 7.16: Probability distributions of ERF to CO_2 doubling ($\Delta F_{2\times CO2}$, top) and the net climate feedback (α, right), derived from process-based assessments in Sections 7.3.2 and 7.4.2. Middle panel shows the joint probability density function calculated on a two-dimensional plane of $\Delta F_{2\times CO2}$ and α (red), on which the 90% range shown by an ellipse is imposed to the background theoretical values of ECS (colour shading). The white dot, thick and thin curves in the ellipse represent the mean, *likely* and *very likely* ranges of ECS. An alternative estimation of the ECS range (pink) is calculated by assuming that $\Delta F_{2\times CO2}$ and α have a covariance. The assumption about the co-dependence between $\Delta F_{2\times CO2}$ and α does not alter the mean estimate of ECS but affects its uncertainty. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

7.5.1.2 Emulating process-based ECS to TCR

ECS estimated using the ERF due to a doubling of CO_2 concentration and the net feedback parameter (ECS = $-\Delta F_{2\times CO2}/\alpha$) can be translated into the TCR so that both climate sensitivity metrics provide consistent information about the climate response to forcing. Here a two-layer energy budget emulator is used to transfer the process-based assessment of forcing, feedback, efficacy and heat uptake to TCR (Supplementary Material 7.SM.2.1, Cross-Chapter Box 7.1). The emulator can reproduce the transient surface temperature evolution in ESMs under *1pctCO2* simulations and other climate change scenarios, despite the very low number of degrees of freedom (Held et al., 2010; Geoffroy et al., 2012, 2013a; Palmer et al., 2018). Using this model with parameters given from assessments in the previous sections, TCR is assessed based on the process-based understanding.

In the two-layer energy balance emulator, additional parameters are introduced: heat capacities of the upper and deep ocean, heat uptake efficiency (γ), and the so-called efficacy parameter (ε) that represents the dependence of radiative feedbacks and heat uptake on the evolving SST pattern under CO_2 forcing alone (Section 7.4.4). In the real world, natural internal variability and aerosol radiative forcing also affect the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

efficacy parameter, but these effects are excluded for the current discussion.

The analytical solution of the energy balance emulator reveals that the global surface temperature change to abrupt increase of the atmospheric CO_2 concentration is expressed by a combination of a fast adjustment of the surface components of the climate system and a slow response of the deep ocean, with time scales of several years and several centuries, respectively (grey curves in Figure 7.17). The equilibrium response of upper ocean temperature, approximating SST and the surface air temperature response, depends, by definition, only on the radiative forcing and the net feedback parameter. Uncertainty in α dominates (80–90%) the corresponding uncertainty range for ECS in CMIP5 models (Vial et al., 2013), and also an increase of ECS in CMIP6 models (Section 7.5.5) is attributed by about 60–80% to a change in α (Zelinka et al., 2020). For the range of TCR, the contribution from uncertainty in α is reduced to 50–60% while uncertainty in $\Delta F_{2\times CO2}$ becomes relatively more important (Geoffroy et al., 2012; Lutsko and Popp, 2019). TCR reflects the fast response occurring approximately during the first 20 years in the *abrupt4xCO2* simulation (Held et al., 2010), but the fast response is not independent of the slow response because there is a nonlinear co-dependence between them (Andrews et al., 2015). The nonlinear relationship between ECS and TCR indicates that the probability of high TCR is not very sensitive to changes in the probability of high ECS (Meehl et al., 2020).

Considering an idealized time evolution of ERF (1% increase per year until CO_2 doubling and held fixed afterwards, see Figure 7.17a), the TCR defined by the surface temperature response at year 70 is derived by substituting the process-based ECS into the analytical solution of the emulator (Figure 7.17b, see also Supplementary Material 7.SM.2.1). When additional parameters in the emulator are prescribed by using CMIP6 multi-model mean values of those estimates (Smith et al., 2020a), this calculation translates the range of ECS in Section 7.5.2.1 to the range of TCR. The transient temperature response, in reality, varies with different estimates of the ocean heat uptake efficiency (γ) and efficacy (ε). When the emulator was calibrated to the transient responses in CMIP5 models, it shows that uncertainty in heat capacities is negligible and differences in γ and ε explain 10–20% of the inter-model spread of TCR among GCMs (Geoffroy et al., 2012). Specifically, their product, $\kappa = \gamma\varepsilon$, appearing in a simplified form of the solution, i.e., $TCR \cong -\Delta F_{2\times CO2}/(\alpha - \kappa)$, gives a single parameter quantifying the damping effects of heat uptake (Jiménez-de-la-Cuesta and Mauritsen, 2019). This parameter is positive and acts to slow down the temperature response in a similar manner to the 'pattern effect' (Sections 7.4.4.3 and 7.5.2.1). The ocean heat uptake in nature is controlled by multiple processes associated with advection and mixing (Exarchou et al., 2014; Kostov et al., 2014; Kuhlbrodt et al., 2015) but is simplified to be represented by a single term of heat exchange between the upper- and deep-ocean in the emulator. Therefore, it is challenging to constrain γ and ε from process-based understanding (Section 7.5.2). Because the estimated values are only weakly correlated across models, the mean value and one standard deviation of κ are calculated as $\kappa = 0.84 \pm 0.38$ W m^{-2} °C^{-1} (one standard deviation) by ignoring their covariance (the mean value is very similar to that used for Chapter 4, Box 4.1, Figure 1) (see Supplementary Material 7.SM.2.1). By incorporating this inter-model spread in κ, the range of TCR is widened by about 10% (blue bar in Figure 7.17b). Yet, the dominant contribution to the uncertainty range of TCR arises from the net feedback parameter α, consistent with analyses of CMIP6 models (Williams et al., 2020), and this assessment remains unchanged from AR5 stating that uncertainty in ocean heat uptake is of secondary importance.

In summary, the process-based estimate of TCR is assessed to have the central value of 2.0°C with the *likely* range from 1.6 to 2.7°C and the *very likely* range from 1.3 to 3.1°C (*high confidence*). The upper bound of the assessed range was slightly reduced from AR5 but can be further constrained using multiple lines of evidence (Section 7.5.5).

7.5.2 Estimates of ECS and TCR based on the instrumental record

This section assesses the estimates of ECS and TCR based on the instrumental record of climate change and variability with an emphasis on new evidence since AR5. Several lines of evidence are assessed including the global energy budget (Section 7.5.2.1), the use of simple climate models evaluated against the historical temperature record (Section 7.5.2.2), and internal variability in global temperature and TOA radiation (Section 7.5.2.3). Section 7.5.2.4 provides an overall assessment of TCR and ECS based on these lines of evidence from the instrumental record.

7.5.2.1 Estimates of ECS and TCR based on the global energy budget

The GSAT change from 1850–1900 to 2006–2019 is estimated to be 1.03 [0.86 to 1.18] °C (Cross-chapter Box 2.3). Together with estimates of Earth's energy imbalance (Section 7.2.2) and the global ERF that has driven the observed warming (Section 7.3), the instrumental temperature record enables global energy budget estimates of ECS and TCR. While energy budget estimates use instrumental data, they are not based purely on observations. A conceptual model typically based on the global-mean forcing and response energy budget framework (Box 7.1) is needed to relate ECS and TCR to the estimates of global warming, ERF and Earth's energy imbalance (Forster, 2016; Knutti et al., 2017). Moreover, ESM simulations partly inform estimates of the historical ERF (Section 7.3) as well as Earth's energy imbalance in the 1850-1900 climate (the period against which changes are measured) (Forster, 2016; Lewis and Curry, 2018). ESMs are also used to estimate uncertainty due the internal climate variability that may have contributed to observed changes in temperature and energy imbalance (e.g., Palmer and McNeall, 2014; Sherwood et al., 2020). Research since AR5 has shown that global energy budget estimates of ECS may be biased low when they do not take into account how radiative feedbacks depend on the spatial pattern of surface warming (Section 7.4.4.3) or when they do not incorporate improvements in the estimation of global surface temperature trends which take better account of data-sparse regions and are more consistent in their treatment of surface temperature data (Chapter 2, Section 2.3.1). Together with updated estimates of global ERF and Earth's energy imbalance, these advances since AR5 have helped to reconcile energy budget estimates of ECS with estimates of ECS from other lines of evidence.

The traditional global-mean forcing and response energy budget framework (Gregory et al., 2002; Section 7.4.1; Box 7.1) relates the difference between the ERF (ΔF) and the radiative response to observed global warming ($\alpha\Delta T$) to the Earth's energy imbalance (ΔN): $\Delta N = \alpha\Delta T + \Delta F$. Given the relationship ECS = $-\Delta F_{2\times CO2}/\alpha$, where $\Delta F_{2\times CO2}$ is the ERF from CO_2 doubling, ECS can be estimated from historical estimates of ΔT, ΔF, ΔN and $\Delta F_{2\times CO2}$: $ECS = \Delta F_{2\times CO2}\,\Delta T/(\Delta F - \Delta N)$. Since TCR is defined as the temperature change at the time of CO_2 doubling under an idealized 1% yr^{-1} CO_2 increase, it can be inferred from the historical record as: $TCR = \Delta F_{2\times CO2}\,\Delta T/\Delta F$, under the assumption that radiative forcing increases quickly compared to the adjustment timescales of the deep ocean, but slowly enough and over a sufficiently long time that the upper ocean is adjusted, so that ΔT and ΔN increases approximately in proportion to ΔF. Because ΔN is positive, TCR is always smaller than ECS, reflecting weaker transient warming than equilibrium warming. TCR is better constrained than ECS owing to the fact that the denominator of TCR, without the quantity ΔN, is more certain and further from zero than is the denominator of ECS. The upper bounds of both TCR and ECS estimated from historical warming are inherently less certain than their lower bounds because ΔF is uncertain and in the denominator.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The traditional energy budget framework lacks a representation of how radiative feedbacks depend on the spatial pattern of warming. Thus, studies employing this framework (Otto et al., 2013; Lewis and Curry, 2015, 2018; Forster, 2016) implicitly assume that the net radiative feedback has a constant magnitude, producing an estimate of the effective ECS (defined as the value of ECS that would occur if α does not change from its current value) rather than of the true ECS. As summarized in Section 7.4.4.3, there are now multiple lines of evidence providing *high confidence* that the net radiative feedback will become less negative as the warming pattern evolves in the future (the pattern effect). This arises because historical warming has been relatively larger in key negative feedback regions (e.g., western tropical Pacific Ocean) and relatively smaller in key positive feedback regions (e.g., eastern tropical Pacific Ocean and Southern Ocean) than is projected in the near-equilibrium response to CO_2 forcing (Held et al., 2010; Proistosescu and Huybers, 2017; Dong et al., 2019; Section 7.4.4.3), implying that the true ECS will be larger than the effective ECS inferred from historical warming. This section first assesses energy budget constraints on TCR and the effective ECS based on updated estimates of historical warming, ERF, and Earth's energy imbalance. It then assesses what these energy budget constraints imply for values of ECS once the pattern effect is accounted for.

Energy budget estimates of TCR and ECS have evolved in the literature over recent decades. Prior to AR4, the global energy budget provided relatively weak constraints, primarily due to large uncertainty in the tropospheric aerosol forcing, giving ranges of the effective ECS that typically included values above 10°C (Forster, 2016; Knutti et al., 2017). Revised estimates of aerosol forcing together with a larger greenhouse-gas forcing by the time of AR5 led to an estimate of ΔF that was more positive and with reduced uncertainty relative to AR4. Using energy budget estimates and radiative forcing estimates updated to 2009, Otto et al. (2013) estimated that TCR was 1.3 [0.9 to 2.0] °C, and that the effective ECS was 2.0 [1.2 to 3.9] °C. This AR5-based energy budget estimate of ECS was lower than estimates based on other lines of evidence, leading AR5 to expand the assessed *likely* range of ECS to include lower values relative to AR4. Studies since AR5 using similar global energy budget methods have produced similar or slightly narrower ranges for TCR and effective ECS (Forster, 2016; Knutti et al., 2017).

Energy budget estimates of TCR and ECS assessed here are based on improved observations and understanding of global surface temperature trends extended to the year 2020 (Chapter 2, Section 2.3.1), revised estimates of Earth's energy imbalance (Section 7.2), and revised estimates of ERF (Section 7.3). Accurate, in situ-based estimates of Earth's energy imbalance can be made from around 2006 based on near-global ocean temperature observations from the ARGO array of autonomous profiling floats (Chapter 2 Section 2.3, Section 7.2). Over the period 2006 to 2018 the Earth's energy imbalance is estimated to be 0.79 ± 0.27 W m^{-2} (Section 7.2) and it is assumed that this value is also representative for the period 2006 to 2019. Anomalies are taken with respect to the baseline period 1850-1900, although other baselines could be chosen to avoid major volcanic activity (Otto et al., 2013; Lewis and Curry, 2018). Several lines of evidence, including ESM simulations (Lewis and Curry, 2015), energy balance modelling (Armour, 2017), inferred ocean warming given observed SSTs using ocean models (Gebbie and Huybers, 2019; Zanna et al., 2019), and ocean warming reconstructed from noble gas thermometry (Baggenstos et al., 2019) suggest a 1850-1900 Earth energy imbalance of 0.2 ± 0.2 W m^{-2}. Combined with estimates of internal variability in Earth's energy imbalance, calculated using periods of equivalent lengths of years as used in unforced ESM simulations (Palmer and McNeall, 2014; Sherwood et al., 2020b), the anomalous energy imbalance between 1850–1900 and 2006–2019 is estimated to be $\Delta N = 0.59 \pm 0.35$ W m^{-2}. GSAT change between 1850–1900 and 2006–2019 is estimated to be $\Delta T = 1.03°C \pm 0.20$ °C (Chapter 2, Cross-Chapter Box 2.3; Box 7.2) after accounting for internal temperature variability derived from unforced ESM simulations (Sherwood et al., 2020b). The ERF change between 1850–1900 and 2006–2019 is estimated to be ΔF = 2.20 [1.53 to 2.91] W m^{-2} (Section 7.3.5) and the ERF for a doubling of CO_2 is estimated to be $\Delta F_{2\times CO2} = 3.93 \pm 0.47$ W m^{-2} (Section 7.3.2). Employing these values within the traditional global energy balance framework described above (following the methods of Otto et al. (2013) and accounting for correlated uncertainties between ΔF and $\Delta F_{2\times CO2}$) produces a TCR of 1.9 [1.3 to 2.7]°C and an effective ECS of 2.5 [1.6–4.8] °C. These TCR and effective ECS values are higher than those in the recent literature (Otto et al., 2013; Lewis and Curry, 2015, 2018) but are comparable to those of Sherwood et al. (2020) who also used updated estimates of observed warming, Earth's energy imbalance, and ERF.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The trend estimation method applied to global surface temperature affects derived values of ECS and TCR from the historical record. In this Report, the effective ECS is inferred from estimates that use global coverage of GSAT to estimate the surface temperature trends. The GSAT trend is assessed to have the same best estimate as the observed global mean surface temperature (GMST), although the GSAT trend is assessed to have larger uncertainty (see Cross-Chapter Box 2.3). Many previous studies have relied on HadCRUT4 GMST estimates that used the blended observations and did not interpolate over regions of incomplete observational coverage such as the Arctic. As a result, the ECS and TCR derived from these studies has smaller ECS and TCR values than those derived from model-inferred estimates (Richardson et al., 2016, 2018a). The energy budget studies assessing ECS in AR5 employed HadCRUT4 or similar measures of GMST trends. As other lines of evidence in that report used GSAT trends, this could partly explain why AR5-based energy budget estimates of ECS were lower than those estimated from other lines of evidence, adding to the overall disparity in Collins et al. (2013a). In this report, GSAT is chosen as the standard measure of global surface temperature to aid comparison with previous model and process-based estimates of ECS, TCR and climate feedbacks (see Cross-Chapter Box 2.3).

The traditional energy budget framework has been evaluated within ESM simulations by comparing the effective ECS estimated under historical forcing with the ECS estimated using regression methods (Box 7.1) under *abrupt4xCO2* (Andrews et al., 2019; Winton et al., 2020). For one CMIP6 model (GFDL-CM4.0), the value of effective ECS derived from historical energy budget constraints is 1.8°C while ECS is estimated to be 5.0°C (Winton et al., 2020). For another model (HadGEM3-GC3.1-LL) the effective ECS derived from historical energy budget constraints is 4.1°C (average of four ensemble members) while ECS is estimated to be 5.5°C (Andrews et al., 2019). These modelling results suggest that the effective ECS under historical forcing could be lower than the true ECS owing to differences in radiative feedbacks induced by the distinct patterns of historical and equilibrium warming (Section 7.4.4.3). Using GFDL-CM4, Winton et al. (2020) also find that the value of TCR estimated from energy budget constraints within a historical simulation (1.3°C) is substantially lower than the true value of TCR (2.1°C) diagnosed within a *1pctCO₂* simulation owing to a combination of the pattern effect and differences in the efficiency of ocean heat uptake between historical and *1pctCO₂* forcing. This section next considers how the true ECS can be estimated from the historical energy budget by accounting for the pattern effect. However, owing to limited evidence this section does not attempt to account for these effects in estimates of TCR.

Research since AR5 has introduced extensions to the traditional energy budget framework that account for the feedback dependence on temperature patterns by allowing for multiple radiative feedbacks operating on different timescales (Armour et al., 2013; Geoffroy et al., 2013a; Armour, 2017; Proistosescu and Huybers, 2017; Goodwin, 2018; Rohrschneider et al., 2019), by allowing feedbacks to vary with the spatial pattern or magnitude of ocean heat uptake (Winton et al., 2010; Rose et al., 2014; Rugenstein et al., 2016a), or by allowing feedbacks to vary with the type of radiative forcing agent (Kummer and Dessler, 2014; Shindell, 2014; Marvel et al., 2016; Winton et al., 2020). A direct way to account for the pattern effect is to use the relationship $ECS = \Delta F_{2\times CO2}/(-\alpha + \alpha')$, where $\alpha = (\Delta N - \Delta F)/\Delta T$ is the effective feedback parameter (Box 7.1) estimated from historical global energy budget changes and α' represents the change in the feedback parameter between the historical period and the equilibrium response to CO_2 forcing, which can be estimated using ESMs (Armour, 2017; Andrews et al., 2018, 2019; Lewis and Curry, 2018; Dong et al., 2020; Winton et al., 2020; Section 7.4.4.3).

The net radiative feedback change between the historical warming pattern and the projected equilibrium warming pattern in response to CO_2 forcing (α') is estimated to be in the range 0.0 to 1.0 W m^{-2} °C^{-1} (Figure 7.15). Using the value $\alpha' = +0.5 \pm 0.5$ W m^{-2} °C^{-1} to represent this range illustrates the effect of changing radiative feedbacks on estimates of ECS. While the effective ECS inferred from historical warming is 2.5 [1.6–4.8] °C , $ECS = \Delta F_{2\times CO2}/(-\alpha + \alpha')$ is 3.5 [1.7–13.8] °C. For comparison, values of α' derived from the response to historical and idealized CO_2 forcing within coupled climate models (Armour, 2017; Lewis and Curry, 2018; Andrews et al., 2019; Dong et al., 2020; Winton et al., 2020) can be approximated as $\alpha' = +0.1 \pm 0.3$ W m^{-2} °C^{-1} (Section 7.4.4.3), corresponding to a value of ECS of 2.7 [1.7–5.9] °C. In both cases, the low end of the ECS range is similar to that of the effective ECS inferred using the traditional energy balance model framework that assumes $\alpha' = 0$, reflecting a weak dependence on the value of α' when ECS is small

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Armour, 2017; Andrews et al., 2018); the low end of the ECS range is robust even in the hypothetical case that α' is slightly negative. However, the high end of the ECS range is substantially larger than that of the effective ECS and strongly dependent on the value of α'.

The values of ECS obtained from the techniques outlined above are all higher than those estimated from both AR5 and recently published estimates (Collins et al., 2013a; Otto et al., 2013; Lewis and Curry, 2015; Forster, 2016; Lewis and Curry, 2018). Four revisions made in this Report are responsible for this increase: (1) An upwards revision of historic global surface temperature trends from newly published trend estimates (Chapter 2, Section 2.3.1); (2) An 8% increase in the ERF for $\Delta F_{2\times CO2}$ (Section 7.3.2); (3) A more negative central estimate of aerosol ERF, which acts to reduce estimates of historical ERF trends; and (4) Accounting for the pattern effect in ECS estimates. Values of ECS provided here are similar to those based on the historical energy budget found in Sherwood et al. (2020), with small differences owing to methodological differences and the use of different estimates of observed warming, Earth's energy imbalance, and ERF.

Overall, there is *high confidence* that the true ECS is higher than the effective ECS as inferred from the historical global energy budget, but there is substantial uncertainty in how much higher because of *limited evidence* regarding how radiative feedbacks may change in the future. While several lines of evidence indicate that $\alpha' > 0$, the quantitative accuracy of feedback changes is not known at this time (Section 7.4.4.3). Global energy budget constraints thus provide *high confidence* in the lower bound of ECS which is not sensitive to the value of α': ECS is *extremely unlikely* to be less than 1.6°C. Estimates of α' that are informed by idealized CO_2 forcing simulations of coupled ESMs (Armour, 2017; Lewis and Curry, 2018; Andrews et al., 2019; Dong et al., 2020; Winton et al., 2020) indicate a median value of ECS of around 2.7°C while estimates of α' that are informed by observed historical sea surface temperature patterns (Andrews et al., 2018) indicate a median value of ECS of around 3.5°C. Owing to large uncertainties in future feedback changes, the historical energy budget currently provides little information about the upper end of the ECS range.

7.5.2.2 Estimates of ECS and TCR based on climate model emulators

Energy budget emulators are far less complex than comprehensive ESMs (see Chapter 1, Section 1.5.3 and Cross-Chapter Box 7.1). For example, an emulator could represent the atmosphere, ocean, and land using a small number of connected boxes (e.g., Goodwin, 2016), or it could represent the global mean climate using two connected ocean layers (e.g., Cross-Chapter Box 7.1, Supplementary Material 7.SM.2). The numerical efficiency of emulators means that they can be empirically constrained by observations: a large number of possible parameter values (e.g., feedback parameter, aerosol radiative forcing, and ocean diffusivity) are randomly drawn from prior distributions; forward integrations of the model are performed with these parameters and weighted against observations of surface or ocean warming, producing posterior estimates of quantities of interest such as TCR, ECS and aerosol forcing (see Section 7.3). Owing to their reduced complexity, emulators lack full representations of the spatial patterns of sea surface temperature and radiative responses to changes in those patterns (discussed in Section 7.4.4.3) and many represent the net feedback parameter using a constant value. The ranges of ECS reported by studies using emulators are thus interpreted here as representative of the effective ECS over the historical record rather than of the true ECS.

Improved estimates of ocean heat uptake over the past two decades (Section 7.2) have diminished the role of ocean diffusivity in driving uncertainty in ECS estimates, leaving the main trade-off between posterior ranges in ECS and aerosol radiative forcing (Forest, 2002; Knutti et al., 2002; Frame et al., 2005). AR5 (Bindoff et al., 2013) assessed a variety of estimates of ECS based on emulators and found that they were sensitive to the choice of prior parameter distributions and temperature datasets used, particularly for the upper end of the ECS range, though priors can be chosen to minimize the effect on results (e.g., Lewis, 2013). Emulators generally produced estimates of effective ECS between 1°C and 5°C and ranges of TCR between 0.9°C and 2.6°C. Padilla et al. (2011) use a simple global-average emulator with two timescales (see Supplementary Material 7.SM.2 and Section 7.5.1.2) to estimate a TCR of 1.6 [1.3 to 2.6] °C. Using the same model, Schwartz (2012) finds TCR in the range 0.9–1.9°C while Schwartz (2018) finds that an effective ECS of 1.7°C provides the best fit to the historical global surface temperature record while also

ACCEPTED VERSION SUBJECT TO FINAL EDITING

finding a median aerosol forcing that is smaller than that assessed in Section 7.3. Using an eight-box representation of the atmosphere–ocean–terrestrial system constrained by historical warming, Goodwin (2016) found an effective ECS of 2.4 [1.4 to 4.4] °C while Goodwin (2018) found effective ECS to be in the range 2–4.3°C when using a prior for ECS based on paleoclimate constraints.

Using an emulator comprised of northern and southern hemispheres and an upwelling-diffusive ocean (Aldrin et al., 2012), with surface temperature and ocean heat content datasets updated to 2014, Skeie et al. (2018) estimate a TCR of 1.4 [0.9 to 2.0] °C and a median effective ECS of 1.9 [1.2 to 3.1] °C. Using a similar emulator comprised of land and ocean regions and an upwelling-diffusive ocean, with global surface temperature and ocean heat content datasets through 2011, Johansson et al. (2015) find an effective ECS of 2.5 [2.0 to 3.2] °C. The estimate is found to be sensitive to the choice of dataset endpoint and the representation of internal variability meant to capture the El Niño–Southern Oscillation and Pacific Decadal Variability. Differences between these two studies arise, in part, from their different global surface temperature and ocean heat content datasets, different radiative forcing uncertainty ranges, different priors for model parameters, and different representations of internal variability. This leads to different estimates of effective ECS, with the median estimate of Skeie et al. (2018) lying below the 5% to 95% range of effective ECS from Johansson et al. (2015). Moreover, while the Skeie et al. (2018) emulator has a constant value of the net feedback parameter, the Johansson et al. (2015) emulator allows distinct radiative feedbacks for land and ocean, contributing to the different results.

The median estimates of TCR and effective ECS inferred from emulator studies generally lie within the 5% to 95% ranges of the those inferred from historical global energy budget constraints (1.3 to 2.7°C for TCR and 1.6 to 4.8°C for effective ECS). Their estimates would be consistent with still higher values of ECS when accounting for changes in radiative feedbacks as the spatial pattern of global warming evolves in the future (Section 7.5.2.1). Cross-Chapter Box 7.1 and references therein show that four very different physically-based emulators can be calibrated to match the assessed ranges of historical GSAT change, ERF, ECS and TCR from across the report. Therefore, the fact that the emulator effective ECS values estimated from previous studies tend to lie at the lower end of the range inferred from historical global energy budget constraints may reflect that the energy budget constraints in Section 7.5.2.1 use updated estimates of Earth's energy imbalance, GSAT trends and ERF, rather than any methodological differences between the lines of evidence. The 'emergent constraints' on ECS based on observations of climate variability used in conjunction with comprehensive ESMs are assessed in Section 7.5.4.1.

7.5.2.3 Estimates of ECS based on variability in Earth's top-of-atmosphere radiation budget

While continuous satellite measurements of TOA radiative fluxes (Figure 7.3) do not have sufficient accuracy to determine the absolute magnitude of Earth's energy imbalance (Section 7.2.1), they provide accurate estimates of its variations and trends since the year 2002 that agree well with estimates based on observed changes in global ocean heat content (Loeb et al., 2012; Johnson et al., 2016; Palmer, 2017). When combined with global surface temperature observations and simple models of global energy balance, satellite measurements of TOA radiation afford estimates of the net feedback parameter associated with recent climate variability (Tsushima and Manabe, 2013; Donohoe et al., 2014; Dessler and Forster, 2018). These feedback estimates, derived from the regression of TOA radiation on surface temperature variability, imply values of ECS that are broadly consistent with those from other lines of evidence (Forster, 2016; Knutti et al., 2017). A history of regression-based feedbacks and their uncertainties is summarized in (Bindoff et al., 2013; Forster, 2016; Knutti et al., 2017).

Research since AR5 has noted that regression-based feedback estimates depend on whether annual- or monthly-mean data are used and on the choice of lag employed in the regression, complicating their interpretation (Forster, 2016). The observed lead-lag relationship between global TOA radiation and global surface temperature, and its dependence on sampling period, is well replicated within unforced simulations of ESMs (Dessler, 2011; Proistosescu et al., 2018). These features arise because the regression between global TOA radiation and global surface temperature reflects a blend of different radiative feedback processes associated with several distinct modes of variability acting on different time scales (Annex IV),

ACCEPTED VERSION SUBJECT TO FINAL EDITING

such as monthly atmospheric variability and inter-annual El Niño–Southern Oscillation (ENSO) variability (Lutsko and Takahashi, 2018; Proistosescu et al., 2018). Regression-based feedbacks thus provide estimates of the radiative feedbacks that are associated with internal climate variability (e.g., Brown et al., 2014), and do not provide a direct estimate of ECS (*high confidence*). Moreover, variations in global surface temperature that do not directly affect TOA radiation may lead to a positive bias in regression-based feedback, although this bias appears to be small, particularly when annual-mean data are used (Murphy and Forster, 2010; Spencer and Braswell, 2010, 2011; Proistosescu et al., 2018). When tested within ESMs, regression-based feedbacks have been found to be only weakly correlated with values of ECS (Chung et al., 2010), although cloudy-sky TOA radiation fluxes have been found to be moderately correlated with ECS at ENSO timescales within CMIP5 models (Lutsko and Takahashi, 2018).

Finding such correlations within models requires simulations that span multiple centuries, suggesting that the satellite record may not be of sufficient length to produce robust feedback estimates. However, correlations between regression-based feedbacks and long-term feedbacks have been found to be higher when focused on specific processes or regions, such as for cloud or the water vapour feedback (Dessler, 2013; Zhou et al., 2015; Section 7.4.2). Assessing the global radiative feedback in terms of the more stable relationship between tropospheric temperature and TOA radiation offers another potential avenue for constraining ECS. The 'emergent constraints' on ECS based on variability in the TOA energy budget are assessed in Section 7.5.4.1.

7.5.2.4 Estimates of ECS based on the climate response to volcanic eruptions

A number of studies consider the observed climate response to volcanic eruptions over the 20th century (Knutti et al., 2017; Chapter 3 Section 3.3.1, Cross-Chapter Box 4.1). However, the direct constraint on ECS is weak, particularly at the high end, because the temperature response to short-term forcing depends only weakly on radiative feedbacks and because it can take decades of a sustained forcing before the magnitude of temperature changes reflects differences in ECS across models (Geoffroy et al., 2013b; Merlis et al., 2014). It is also a challenge to separate the response to volcanic eruptions from internal climate variability in the years that follow them (Wigley et al., 2005). Based on ESM simulations, radiative feedbacks governing the global surface temperature response to volcanic eruptions can be substantially different than those governing long-term global warming (Merlis et al., 2014; Marvel et al., 2016; Ceppi and Gregory, 2019). Estimates based on the response to volcanic eruptions agree with other lines of evidence (Knutti et al., 2017), but they do not constitute a direct estimate of ECS (*high confidence*). The 'emergent constraints' on ECS based on climate variability, including volcanic eruptions, are summarized in Section 7.5.4.1.

7.5.2.5 Assessment of ECS and TCR based on the instrumental record

Evidence from the instrumental temperature record, including estimates using global energy budget changes (Section 7.5.2.1), climate emulators (Section 7.5.2.2), variability in the TOA radiation budget (Section 7.5.2.3), and the climate response to volcanic eruptions (Section 7.5.2.4) produce median ECS estimates that range between 2.5°C and 3.5°C, but a best estimate value cannot be given owing to a strong dependence on assumptions about how radiative feedbacks will change in the future. However, there is *robust evidence* and *high agreement* across the lines of evidence that ECS is *extremely likely* greater than 1.6°C (*high confidence*). There is *robust evidence* and *medium agreement* across the lines of evidence that ECS is *very likely* greater than 1.8°C and *likely* greater than 2.2°C (*high confidence)*. These ranges of ECS correspond to estimates based on historical global energy budget constraints (Section 7.5.2.1) under the assumption of no feedback dependence on evolving SST patterns (i.e., $\alpha' = 0$) and thus represent an underestimate of the true ECS ranges that can be inferred from this line of evidence (*high confidence*). Historical global energy budget changes do not provide constraints on the upper bound of ECS, while the studies assessed in Section 7.5.2.3 based on climate variability provide *low confidence* in its value owing to *limited evidence*.

Global energy budget constraints indicate a central estimate (median) TCR value of 1.9°C and that TCR is *likely* in the range 1.5°C to 2.3°C and *very likely* in the range 1.3°C to 2.7°C (*high confidence*). Studies that

ACCEPTED VERSION SUBJECT TO FINAL EDITING

constrain TCR based on the instrumental temperature record used in conjunction with ESM simulations are summarized in Section 7.5.4.3.

7.5.3 Estimates of ECS based on paleoclimate data

Estimates of ECS based on paleoclimate data are complementary to, and largely independent from, estimates based on process-based studies (Section 7.5.1) and the instrumental record (Section 7.5.2). The strengths of using paleoclimate data to estimate ECS include: (1) the estimates are based on observations of a real-world Earth system response to a forcing, in contrast to using estimates from process-based modelling studies or directly from models; (2) the forcings are often relatively large (similar in magnitude to a CO_2 doubling or more), in contrast to data from the instrumental record; (3) the forcing often changes relatively slowly so the system is close to equilibrium; as such, all individual feedback parameters, α_x, are included, and complications associated with accounting for ocean heat uptake are reduced or eliminated, in contrast to the instrumental record. However, there can be relatively large uncertainties on estimates of both the paleo forcing and paleo global surface temperature response, and care must be taken to account for long-term feedbacks associated with ice sheets (Section 7.4.2.6), which often play an important role in the paleoclimate response to forcing, but which are not included in the definition of ECS. Furthermore, the state-dependence of feedbacks (Section 7.4.3) means that climate sensitivity during Earth's past may not be the same as it is today, which should be accounted for when interpreting paleoclimate estimates of ECS.

AR5 stated that data and modelling of the Last Glacial Maximum (LGM, Cross-Chapter Box 2.1) indicated that it was *very unlikely* that ECS lay outside the range 1–6°C (Masson-Delmotte et al., 2013). Furthermore, AR5 reported that climate records of the last 65 million years indicated an ECS 95% confidence interval of 1.1–7.0°C.

Compared with AR5, there are now improved constraints on estimates of ECS from paleoclimate evidence. The strengthened understanding and improved lines of evidence come in part from the use of high-resolution paleoclimate data across multiple glacial-interglacial cycles, taking into account state-dependence (von der Heydt et al., 2014; Köhler et al., 2015, 2017, 2018; Friedrich et al., 2016; Snyder, 2019; Stap et al., 2019; Section 7.4.3) and better constrained pre-ice core estimates of atmospheric CO_2 concentrations (Martínez-Botí et al., 2015; Anagnostou et al., 2016, 2020; de la Vega et al., 2020) and surface temperature (Hollis et al., 2019; Inglis et al., 2020; McClymont et al., 2020).

Overall, the paleoclimate lines of evidence regarding climate sensitivity can be broadly categorised into two types: estimates of radiative forcing and temperature response from paleo proxy measurements, and emergent constraints on paleoclimate model simulations. This section focuses on the first type only; the second type (emergent constraints) are discussed in Section 7.5.4.

In order to provide estimates of ECS, evidence from the paleoclimate record can be used to estimate forcing (ΔF) and global surface temperature response (ΔT) in Equation 7.1, Box 7.1, under the assumption that the system is in equilibrium (i.e. ΔN=0). However, there are complicating factors when using the paleoclimate record in this way, and these challenges and uncertainties are somewhat specific to the time period being considered.

7.5.3.1 Estimates of ECS from the Last Glacial Maximum

The LGM (Cross-Chapter Box 2.1) has been used to provide estimates of ECS (Sherwood et al., 2020b; Tierney et al., 2020b) (see Table 7.11 for estimates since AR5). The major forcings and feedback processes that led to the cold climate at that time (e.g., CO_2, non-CO_2 greenhouse gases, and ice sheets) are relatively well-known (Chapter 5, Section 5.1), orbital forcing relative to pre-industrial was negligible, and there are relatively high spatial resolution and well-dated paleoclimate temperature data available for this time period (Chapter 2, Section 2.3.1). Uncertainties in deriving global surface temperature from the LGM proxy data arise partly from uncertainties in the calibration from the paleoclimate data to local annual mean surface

ACCEPTED VERSION SUBJECT TO FINAL EDITING

temperature, and partly from uncertainties in the conversion of the local temperatures to an annual mean global surface temperature. Overall, the global mean LGM cooling relative to pre-industrial is assessed to be *very likely* from 5–7°C (Chapter 2, Section 2.3.1). The LGM climate is often assumed to be in full equilibrium with the forcing, such that ΔN in Equation 7.1, Box 7.1, is zero. A calculation of sensitivity using solely CO_2 forcing, and assuming that the LGM ice sheets were in equilibrium with that forcing, would give an Earth System Sensitivity (ESS) rather than an ECS (see Box 7.1). In order to calculate an ECS, which is defined here to include all feedback processes except ice sheets, the approach of Rohling et al. (2012) can be used. This approach introduces an additional forcing term in Equation 7.1, Box 7.1, that quantifies the resulting forcing associated with the ice sheet feedback (primarily an estimate of the radiative forcing associated with the change in surface albedo). However, differences between studies as to which processes are considered as forcings (for example, some studies also include vegetation and/or aerosols, such as dust, as forcings), means that published estimates are not always directly comparable. Additional uncertainty arises from the magnitude of the ice sheet forcing itself (Stap et al., 2019; Zhu and Poulsen, 2021), which is often estimated using ESMs. Furthermore, the ECS at the LGM may differ from that of today due to state-dependence (see Section 7.4.3). Here, only studies that report values of ECS that have accounted for the long-term feedbacks associated with ice sheets, and therefore most closely estimate ECS as defined in this chapter, are assessed here (see Table 7.11).

7.5.3.2 Estimates of ECS from glacial-interglacial cycles

Since AR5, several studies have extended the Rohling et al. (2012) approach (described above for the LGM) to the glacial-interglacial cycles of the last ~1 to 2 million years (von der Heydt et al., 2014; Köhler et al., 2015; Friedrich et al., 2016; Royer, 2016; Köhler et al., 2017, 2018; Snyder, 2019; Stap et al., 2019; Friedrich and Timmermann, 2020; Table 7.11). Compared to the LGM, uncertainties in the derived ECS from these periods are in general greater, due to greater uncertainty in global surface temperature (due to fewer individual sites with proxy temperature records), ice sheet forcing (due to a lack of detailed ice sheet reconstructions), and CO_2 forcing (for those studies that include the pre-ice core period, where CO_2 reconstructions are substantially more uncertain). Furthermore, accounting for varying orbital forcing in the traditional global-mean forcing and response energy budget framework (Box 7.1) is challenging (Schmidt et al., 2017b), due to seasonal and latitudinal components of the forcing that, despite a close-to-zero orbital forcing in the global annual mean, can directly result in responses in annual mean global surface temperature (Liu et al., 2014), ice volume (Abe-Ouchi et al., 2013), and feedback processes such as those associated with methane (Singarayer et al., 2011). In addition, for time periods in which the forcing relative to the modern era is small (interglacials), the inferred ECS has relatively large uncertainties because the forcing and temperature response (ΔF and ΔT in Equation 7.1 in Box 7.1) are both close to zero.

7.5.3.3 Estimates of ECS from warm periods of the pre-Quaternary

In the pre-Quaternary (prior to about 2.5 million years ago), the forcings and response are generally of the same sign and similar magnitude as future projections of climate change (Burke et al., 2018; Tierney et al., 2020a). Similar uncertainties as for the LGM apply, but in this case a major uncertainty relates to the forcing, because prior to the ice core record there are only indirect estimates of CO_2 concentration. However, advances in pre-ice-core CO_2 reconstruction (e.g., Foster and Rae, 2016; Super et al., 2018; Witkowski et al., 2018) mean that the estimates of pre-Quaternary CO_2 have less uncertainty than at the time of AR5, and these time periods can now contribute to an assessment of climate sensitivity (see Table 7.11). The mid-Pliocene warm period (MPWP; Cross-Chapter Box 2.1; Cross-Chapter Box 2.4) has been targeted for constraints on ECS (Martínez-Botí et al., 2015; Sherwood et al., 2020b), due to the fact that CO_2 concentrations were relatively high at this time (350–425 ppm) and because the MPWP is sufficiently recent that topography and continental configuration are similar to modern-day. As such, a comparison of the MPWP with the pre-industrial climate provides probably the closest natural geological analogue for the modern day that is useful for assessing constraints on ECS, despite the effects of different geographies not being negligible (global surface temperature patterns; ocean circulation). Furthermore, the global surface temperature of the MPWP was such that non-linearities in feedbacks (Section 7.4.3) were relatively modest.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Within the MPWP, the KM5c interglacial has been identified as a particularly useful time period for assessing ECS (Haywood et al., 2013, 2016b) because Earth's orbit during that time was very similar to that of the modern-day.

Further back in time, in the early Eocene (Cross-Chapter Box 2.1), uncertainties in forcing and temperature change become larger, but the signals are generally larger too (Anagnostou et al., 2016, 2020; Shaffer et al., 2016; Inglis et al., 2020). Caution must be applied when estimating ECS from these time periods, due to differing continental position and topography/bathymetry (Farnsworth et al., 2019), and due to temperature-dependence of feedbacks (Section 7.4.3). On even longer timescales of the last 500 million years (Royer, 2016) the temperature and CO_2 measurements are generally asynchronous, presenting challenges in using this information for assessments of ECS.

7.5.3.4 Synthesis of ECS based on paleo radiative forcing and temperature

The lines of evidence directly constraining ECS from paleoclimates are summarised in Table 7.11. Although some of the estimates in Table 7.11 are not independent because they use similar proxy records to each other (e.g., von der Heydt et al., 2014; Köhler et al., 2015, 2017; Stap et al., 2019), there are still multiple independent lines of paleoclimate evidence regarding ECS, from differing past time periods (LGM (Sherwood et al., 2020b; Tierney et al., 2020b); glacial-interglacial (Royer, 2016; Köhler et al., 2017; Snyder, 2019; Friedrich and Timmermann, 2020), Pliocene (Martínez-Botí et al., 2015; Sherwood et al., 2020b) and the Eocene (Anagnostou et al., 2016, 2020; Shaffer et al., 2016; Inglis et al., 2020), with differing proxies for estimating forcing (e.g., CO_2 from ice cores or boron isotopes) and response (e.g., global surface temperature from $\delta^{18}O$, Mg/Ca or Antarctic δD). Furthermore, although different studies have uncertainty estimates that account for differing sources of uncertainty, some studies (Snyder, 2019; Inglis et al., 2020; Sherwood et al., 2020b; Tierney et al., 2020b) do consider many of the uncertainties discussed in Sections 7.5.3.1-7.5.3.3. All the studies based on glacial-interglacial cycles account for some aspects of the state-dependence of climate sensitivity (Section 7.4.3) by considering only the warm phases of the Pleistocene, although what constitutes a warm phase is defined differently across the studies.

[START TABLE 7.11 HERE]

Table 7.11: Estimates of ECS derived from paleoclimates: from AR5 (above double lines) and from post-AR5 studies (below double lines). Many studies provide an estimate of ECS that includes only CO_2 and the ice sheet feedback as forcings, providing an estimate of $S_{[CO2, LI]}$ using the notation of Rohling et al. (2012), which is equivalent to our definition of ECS (Box 7.1). However, some studies provide estimates of other types of sensitivity (column 4). Different studies (column 1) focus on different time periods (column 2) and use a variety of different paleoclimate proxies and models (column 3) to give a best estimate (column 5) and/or a range (column 5). The published ranges given account for varying sources of uncertainty (column 6). See Cross-Chapter Box 2.1 for definition of time periods. All temperature values in column (5) are shown to a precision of 1 decimal place.

(1) Study	(2) Time period	(3) Proxies/models used for CO_2, temperature (T), and global scaling (GS).	(4) Climate sensitivity classification according to Rohling et al. (2012).	(5) Published best estimate of ECS [and/or range]	(6) Range accounts for:

Notes:

(Note 1) S^a in this table denotes a classification of climate sensitivity following (Rohling et al., 2012).

(Note 2) * – Although our assessed value of ERF due to CO_2 doubling is 3.93 W m^{-2} (Section 7.3.2.1), for these studies the best estimate and range of temperature is calculated from the published estimate of sensitivity in units of °C (W m^{-2})$^{-1}$ using an ERF of 3.7 W m^{-2}, for consistency with the typical value used in the studies to estimate the paleo CO_2 forcing.

[END TABLE 7.11 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

None of the post-AR5 studies in Table 7.11 have an estimated lower range for ECS below 1.6 °C. As such, based solely on the paleoclimate record, it is assessed to be *very likely* that ECS is greater than 1.5°C (*high confidence*).

In general, it is the studies based on the warm periods of the glacial-interglacial cycles (Section 7.5.3.2) that give the largest values of ECS. Given the large uncertainties associated with estimating the magnitude of the ice sheet forcing during these intervals (Stap et al., 2019), and other uncertainties discussed in Section 7.5.3.2, in particular the direct effect of orbital forcing on estimates of ECS, there is only *low confidence* in estimates from the studies based on glacial-interglacial periods. This *low confidence* also results from the temperature-dependence of the net feedback parameter, α, resulting from several of these studies (Figure 7.10), that is hard to reconcile with the other lines of evidence for α, including proxy estimates from warmer paleoclimates (Section 7.4.3.2). A central estimate of ECS, derived from the LGM (Section 7.5.3.1) and warm periods of the pre-Quaternary (Section 7.5.3.3), that takes into account some of the interdependencies between the different studies, can be obtained by averaging across studies within each of these two time periods, and then averaging across the two time periods; this results in a central estimate of 3.4°C. This approach of focussing on the LGM and warm climates was also taken by Sherwood et al. (2020) in their assessment of ECS from paleoclimates. An alternative method is to average across all studies, from all periods, that have considered multiple sources of uncertainty (Table 7.11); this approach leads to a similar central estimate of 3.3°C. Overall, we assess *medium confidence* for a central estimate of 3.3–3.4°C.

There is more variation in the upper bounds of ECS than in the lower bounds. Estimates of ECS from pre-Quaternary warm periods have an average upper range of 4.9 °C, and from the LGM of 4.4°C; taking into account the independence of the estimates from these two time periods, and accounting for state-dependence (Section 7.4.3) and other uncertainties discussed in Section 7.5.3, the paleoclimate record on its own indicates that ECS is *likely* less than 4.5 °C. Given the higher values from many glacial-interglacial studies, this value has only *medium confidence*. Despite the large variation in individual studies at the extreme upper end, all except two studies (both of which are from glacial-interglacial time periods associated with *low confidence*) have central estimates that are below 6 °C; overall we assess that it is *extremely likely* that ECS is below 8 °C (*high confidence*).

7.5.4 Estimates of ECS and TCR based on emergent constraints

ESMs exhibit substantial spread in ECS and TCR (Section 7.5.7). Numerous studies have leveraged this spread in order to narrow estimates of Earth's climate sensitivity by employing methods known as “emergent constraints” (Chapter 1, Section 1.5.4). These methods establish a relationship between an observable and either ECS or TCR based on an ensemble of models, and combine this information with observations to constrain the probability distribution of ECS or TCR. Most studies of this kind have clearly benefitted from the international efforts to coordinate the CMIP and other multi-model ensembles.

A number of considerations must be taken into account when assessing the diverse literature on ECS and TCR emergent constraints. For instance, it is important to have physical and theoretical basis for the connection between the observable and modelled ECS or TCR since in model ensembles thousands of relationships that pass statistical significance can be found simply by chance (Caldwell et al., 2014). It is also important that the underlying model ensemble does not exhibit a shared bias that influences the simulation of the observable quantity on which the emergent constraint is based. Also, correctly accounting for uncertainties in both the observable (including measurement uncertainty and natural variability) and the emergent constraint statistical relationship can be challenging, in particular in cases where the latter is not expected to be linear (Annan et al., 2020a). A number of proposed emergent constraints leverage variations in modelled ECS arising from tropical low clouds, which was the dominant source of inter-model spread in the CMIP5 ensemble used in most emergent constraint studies. Since ECS is dependent on the sum of individual feedbacks (Section 7.5.1) these studies implicitly assume that all other feedback processes in models are unbiased and should therefore rather be thought of as constraints on tropical low-cloud feedback (Klein and Hall, 2015; Qu et al., 2018; Schlund et al., 2020). The following sections go through a range of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

emergent constraints and assess their strengths and limitations.

7.5.4.1 Emergent constraints using global or near-global surface temperature change

Perhaps the simplest class of emergent constraints regress past equilibrium paleoclimate temperature change against modelled ECS to obtain a relationship that can be used to translate a past climate change to ECS. The advantage is that these are constraints on the sum of all feedbacks, and furthermore unlike constraints on the instrumental record they are based on climate states that are at, or close to, equilibrium. So far, these emergent constraints have been limited to the Last Glacial Maximum (LGM; Cross-Chapter Box 2.1) cooling (Hargreaves et al., 2012; Schmidt et al., 2014; Renoult et al., 2020) and warming in the mid-Pliocene Warm Period (MPWP, Hargreaves and Annan, 2016; Renoult et al., 2020; Cross-Chapter Box 2.1; Cross-Chapter Box 2.4) due to the availability of sufficiently large multi-model ensembles for these two cases. The paleoclimate emergent constraints are limited by structural uncertainties in the proxy-based global surface temperature and forcing reconstructions (Section 7.5.3), possible differences in equilibrium sea-surface temperature patterns between models and the real world, and a small number of model simulations participating, which has led to divergent results. For example, Hopcroft and Valdes (2015) repeated the study based on the LGM by Hargreaves et al. (2012) using another model ensemble and found that the emergent constraint was not robust, whereas studies using multiple available ensembles retain useful constraints (Schmidt et al., 2014; Renoult et al., 2020). Also, the results are somewhat dependent on the applied statistical methods (Hargreaves and Annan, 2016). However, Renoult et al. (2020) explored this and found 95th percentiles of ECS below 6°C for LGM and Pliocene individually, regardless of statistical approach, and by combining the two estimates the 95th percentile dropped to 4.0°C. The consistency between the cold LGM and warm MPWP emergent constraint estimates increases confidence in these estimates, and further suggests that the dependence of feedback on climate mean state (Section 7.4.3) as represented in PMIP models used in these studies is reasonable.

Various emergent constraint approaches using global warming over the instrumental record have been proposed. These benefit from more accurate data compared with paleoclimates, but suffer from the fact that the climate is not in equilibrium, thereby assuming that ESMs on average accurately depict the ratio of short term to long term global warming. Global warming in climate models over 1850 to the present day exhibits no correlation with ECS, which is partly due to a substantial number of models exhibiting compensation between a high climate sensitivity with strong historical aerosol cooling (Kiehl, 2007; Forster et al., 2013; Nijsse et al., 2020). However, the aerosol cooling increased up until the 1970s when air quality regulations reduced the emissions from Europe and North America whereas other regions saw increases resulting in a subsequently reduced pace of global mean aerosol ERF increase (Chapter 2, Section 2.2.8, Figure 2.10). Energy balance considerations over the 1970–2010 period gave a best estimate ECS of 2.0°C (Bengtsson and Schwartz, 2013), however this estimate did not account for pattern effects. To address this limitation an emergent constraint on 1970–2005 global warming was demonstrated to yield a best estimate ECS of 2.83 [1.72 to 4.12] °C (Jiménez-de-la-Cuesta and Mauritsen, 2019). The study was followed up using CMIP6 models yielding a best estimate ECS of 2.6 [1.5 to 4.0] °C based on 1975–2019 global warming (Nijsse et al., 2020), thereby confirming the emergent constraint. Internal variability and forced or unforced pattern effects may influence the results (Jiménez-de-la-Cuesta and Mauritsen, 2019; Nijsse et al., 2020). For instance the Atlantic Multidecadal Oscillation changed from negative to positive anomaly, while the Indo-Pacific Oscillation changed less over the 1970–2005 period, potentially leading to high-biased results (Jiménez-de-la-Cuesta and Mauritsen, 2019), whereas during the later period 1975–2019 these anomalies roughly cancel (Nijsse et al., 2020). Pattern effects may have been substantial over these periods (Andrews et al., 2018), however the extent to which TOA radiation anomalies influenced surface temperature may have been dampened by the deep ocean (Hedemann et al., 2017; Newsom et al., 2020). It is therefore deemed *more likely than not* that these estimates based on post-1970s global warming are biased low by internal variability.

A study that developed an emergent constraint based on the response to the Mount Pinatubo 1991 eruption yielded a best estimate of 2.4 [*likely* range 1.7–4.1] °C (Bender et al., 2010). When accounting for ENSO variations they found a somewhat higher best estimate of 2.7°C, which is in line with results of later studies

ACCEPTED VERSION SUBJECT TO FINAL EDITING

that suggest ECS inferred from periods with substantial volcanic activity are low-biased due to strong pattern effects (Gregory et al., 2020) and that the short-term nature of volcanic forcing could exacerbate possible underestimates of modelled pattern effects.

Lagged-correlations present in short term variations in the global surface temperature can be linked to ECS through the fluctuation-dissipation theorem which is derived from a single heat reservoir model (Einstein, 1905; Hasselmann, 1976; Schwartz, 2007; Cox et al., 2018a). From this it follows that the memory carried by the heat capacity of the ocean results in low-frequency global temperature variability (red noise) arising from high frequency (white noise) fluctuations in the radiation balance, e.g., caused by weather. Initial attempts to apply the theorem to observations yielded a fairly low median ECS estimate of 1.1°C (Schwartz, 2007), a result that was disputed (Foster et al., 2008; Knutti et al., 2008). Recently it was proposed by Cox et al. (2018a) to use variations in the historical experiments of the CMIP5 climate models as an emergent constraint giving a median ECS estimate of 2.8 [1.6 to 4.0] °C. A particular challenge associated with these approaches is to separate short-term from long-term variability, and slightly arbitrary choices regarding the methodology of separating these in the global surface temperature from long-term signals in the historical record, omission of the more strongly forced period after 1962, as well as input data choices, can lead to median ECS estimates ranging from 2.5–3.5°C (Brown et al., 2018; Po-Chedley et al., 2018b; Rypdal et al., 2018). Calibrating the emergent constraint using CMIP5 modelled internal variability as measured in historical control simulations (Po-Chedley et al., 2018b) will inevitably lead to an overestimated ECS due to externally forced short term variability present in the historical record (Cox et al., 2018b). Contrary to constraints based on paleoclimates or global warming since the 1970s, when based on CMIP6 models a higher, yet still well-bounded ECS estimate of 3.7 [2.6 to 4.8] °C is obtained (Schlund et al., 2020). A more problematic issue is raised by (Annan et al., 2020b) who showed that the upper bound on ECS estimated this way is less certain when considering deep ocean heat uptake. In conclusion, even if not inconsistent, these limitations prevents us from directly using this type of constraint in the assessment.

Short term variations in the TOA energy budget, observable from satellites, arising from variations in the tropical tropospheric temperature has been linked to ECS through models, either as a range of models consistent with observations (those with ECS values between 2.0°C and 3.9°C) (Dessler et al., 2018) or as a formal emergent constraint by deriving further model-based relationships to yield a median of 3.3 [2.4 to 4.5] °C (Dessler and Forster, 2018). There are major challenges associated with short term variability in the energy budget, in particular how it relates to the long-term forced response of clouds (Colman and Hanson, 2017; Lutsko and Takahashi, 2018), and variations in the surface temperature that are not directly affecting the radiation balance lead to an overestimated ECS when using linear regression techniques where it appears as noise in the independent variable (Proistosescu et al., 2018; Gregory et al., 2020). The latter issue is largely overcome when using the tropospheric mean or mid-tropospheric temperature (Trenberth et al., 2015; Dessler et al., 2018).

7.5.4.2 Emergent constraints focused on cloud feedbacks and present-day climate

A substantial number of emergent constraint studies focus on observables that are related to tropical low-cloud feedback processes (Volodin, 2008; Sherwood et al., 2014; Zhai et al., 2015; Brient and Schneider, 2016; Brient et al., 2016). These studies yield median ECS estimates of 3.5–4°C and in many cases indicate low likelihoods of values below 3°C. The approach has attracted attention since most of the spread in climate sensitivity seen in CMIP5, and earlier climate model ensembles, arises from uncertainty in low cloud feedbacks (Bony and Dufresne, 2005; Wyant et al., 2006; Randall et al., 2007; Vial et al., 2013). Nevertheless, this approach assumes that all other feedback processes are unbiased (Klein and Hall, 2015; Qu et al., 2018; Schlund et al., 2020), for instance the possibly missing negative anvil area feedback or the possibly exaggerated mixed-phase cloud feedback (Section 7.4.2.4). Thus, the subset of emergent constraints that focus on low-level tropical clouds are not necessarily inconsistent with other emergent constraints of ECS. Related emergent constraints that focus on aspects of the tropical circulation and ECS have led to conflicting results (Su et al., 2014; Tian, 2015; Lipat et al., 2017; Webb and Lock, 2020), possibly because these processes are not the dominant factors in causing the inter-model spread (Caldwell et al., 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The fidelity of models in reproducing aspects of temperature variability or the radiation budget has also been proposed as emergent constraints on ECS (Covey et al., 2000; Knutti et al., 2006; Huber et al., 2010; Bender et al., 2012; Brown and Caldeira, 2017; Siler et al., 2018a). Here indices based on spatial or seasonal variability are linked to modelled ECS, and overall the group of emergent constraints yields best estimates of 3.3°C to 3.7°C. Nevertheless, the physical relevance of present-day biases to the sum of long-term climate change feedbacks is unclear and therefore these constraints on ECS are not considered reliable.

7.5.4.3 Assessed ECS and TCR based on emergent constraints

The available emergent constraint studies have been divided into two classes: (i) those that are based on global or near-global indices, such as global surface temperature and the TOA energy budget; and (ii) those that are more focussed on physical processes, such as the fidelity of phenomena related to low-level cloud feedbacks or present-day climate biases. The former class is arguably superior in representing ECS, since it is a global surface temperature or energy budget change, whereas the latter class is perhaps best thought of as providing constraints on individual climate feedbacks, e.g., the determination that low-level cloud feedbacks are positive. The latter result is consistent with and confirms process-based estimates of low cloud feedbacks (Section 7.4.2.4), but are potentially biased as a group by missing or biased feedbacks in ESMs and is accordingly not taken into account here. A limiting case here is Dessler and Forster (2018) which is focused on monthly co-variability in the global TOA energy budget with mid-tropospheric temperature, at which time scale the surface albedo feedback is unlikely to operate thus implicitly assuming it is unbiased in the model ensemble.

In the first group of emergent constraints there is broad agreement on the best estimate of ECS ranging from 2.4–3.3°C. At the lower end, nearly all studies find lower bounds (5th percentiles) around 1.5°C, whereas several studies indicate 95th percentiles as low as 4°C. Considering both classes of studies, none of them yield upper *very likely* bounds above 5°C. Since several of the emergent constraints can be considered nearly independent one could assume that emergent constraints provide very strong evidence on ECS by combining them. Nevertheless, this is not done here because there are sufficient cross-dependencies, as for instance models are re-used in many of the derived emergent constraints, and furthermore the methodology has not yet reached a sufficient level of maturity since systematic biases may not have been accounted for. Uncertainty is therefore conservatively added to reflect these potential issues. This leads to the assessment that ECS inferred from emergent constraints is *very likely* 1.5 to 5°C with *medium confidence*.

Emergent constraints on TCR with a focus on the instrumental temperature record, though less abundant, have also been proposed. These can be influenced by internal variability and pattern effects as discussed in Section 7.5.4.1, although the influence is smaller because uncertainty in forced pattern effects correlate between transient historical warming and TCR. In the simplest form Gillett et al. (2012) regressed the response of one model to individual historical forcing components to obtain a tight range of 1.3–1.8°C, but later when an ensemble of models was used the range was widened to 0.9–2.3°C (Gillett et al., 2013), and updated by Schurer et al. (2018). A related data-assimilation based approach that accounted also for uncertainty in response patterns gave 1.33–2.36°C (Ribes et al., 2021), but is dependent on the choice of prior ensemble distribution (CMIP5 or CMIP6). Another study used the response to the Pinatubo volcanic eruption to obtain a range of 0.8–2.3°C (Bender et al., 2010). A tighter range, notably at the lower end, was found in an emergent constraint focusing on the post-1970s warming exploiting the lower spread in aerosol forcing change over this period (Jiménez-de-la-Cuesta and Mauritsen, 2019). Their estimate was 1.67 [1.17 to 2.16] °C. Two studies tested this idea: Tokarska et al. (2020) estimates TCR was 1.60 [0.90 to 2.27] °C based on CMIP6 models, whereas Nijsse et al. (2020) found 1.68 [1.0 to 2.3] °C, and in both cases there was a small sensitivity to choice of ensemble with CMIP6 models yielding slightly lower values and ranges. Combining these studies gives a best estimate of 1.7°C and a *very likely* range of TCR of 1.1–2.3°C with *high confidence*.

7.5.5 Combined assessment of ECS and TCR

Substantial quantitative progress has been made in interpreting evidence of Earth's climate sensitivity since AR5, through innovation, scrutiny, theoretical advances and a rapidly evolving data base from current, recent and paleo climates. It should be noted that, unlike AR5 and earlier reports, our assessment of ECS is not directly informed by ESM simulations (Section 7.5.6). The assessments of ECS and TCR are focussed on the following lines of evidence: process-understanding; the instrumental record of warming; paleoclimate evidence; and emergent constraints. ESMs remain essential tools throughout establishing these lines of evidence, for instance for estimating part of the feedback parameters and radiative forcings, and emergent constraints rely on substantial model spread in ECS and TCR (Section 7.5.6).

A key advance over the AR5 assessment is the broad agreement across multiple lines of evidence. These support a central estimates of ECS close to, or at least not inconsistent with, 3°C. This advance is foremost following improvements in the understanding and quantification of Earth's energy imbalance, the instrumental record of global temperature change, and the strength of anthropogenic radiative forcing. Further advances include increased understanding of how the pattern effect influences ECS inferred from historical global warming (Sections 7.4.4 and 7.5.3), improved quantification of paleo climate change from proxy evidence and a deepened understanding of how feedback mechanisms increase ECS in warmer climate states (Sections 7.4.3, 7.4.4 and 7.5.4), and also an improved quantification of individual cloud feedbacks (Sections 7.4.2 and 7.5.4.2). The assessment findings for ECS and TCR are summarized in Table 7.13 and Table 7.14, respectively, and also visualized in Figure 7.18.

[START FIGURE 7.18 HERE]

Figure 7.18: Summary of the equilibrium climate sensitivity (ECS) and transient climate response (TCR)

ACCEPTED VERSION SUBJECT TO FINAL EDITING

assessments using different lines of evidence. Assessed ranges are taken from Tables 7.13 and 7.14 for ECS and TCR respectively. Note that for the ECS assessment based on both the instrumental record and paleoclimates, limits (i.e. one-sided distributions) are given, which have twice the probability of being outside the maximum/minimum value at a given end, compared to ranges (i.e. two tailed distributions) which are given for the other lines of evidence. For example, the *extremely likely* limit of greater than 95% probability corresponds to one side of the *very likely* (5% to 95%) range. Best estimates are given as either a single number or by a range represented by grey box. CMIP6 model values are not directly used as a line of evidence but presented on the Figure for comparison. ECS values are taken from Schlund et al. (2020) and TCR values from Meehl et al. (2020), see Supplementary Material 7.SM.4. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.18 HERE]

AR5 assessed ECS to have a *likely* range from 1.5 to 4.5°C (Collins et al., 2013a) based on the majority of studies and evidence available at the time. The broader evidence base presented in this Report and the general agreement among different lines of evidence means that they can be combined to yield a narrower range of ECS values. This can be done formally using Bayesian statistics, though such a process is complex and involves formulating likelihoods and priors (Annan and Hargreaves, 2006; Stevens et al., 2016; Sherwood et al., 2020b). However, it can be understood that if two lines of independent evidence each give a low probability of an outcome being true, e.g., that ECS is less than 2.0°C, then the combined probability that ECS is less than 2.0°C is lower than that of either line of evidence. On the contrary, if one line of evidence is unable to rule out an outcome, but another is able to assign a low probability, then there is a low probability that the outcome is true (Stevens et al., 2016). This general principle applies even when there is some dependency between the lines of evidence (Sherwood et al., 2020b), for instance between historical energy budget constraints (Section 7.5.2.1) and those emergent constraints that use the historically observed global warming (Section 7.5.4.1). Even in this case the combined constraint will be closer to the narrowest range associated with the individual lines of evidence.

In the process of providing a combined and self-consistent ECS assessment across all lines of evidence, the above principles were all considered. As in earlier reports, a 0.5°C precision is used. Starting with the *very likely* lower bound, there is broad support for a value of 2.0°C, including process understanding and the instrumental record (Table 7.13). For the *very likely* upper bound, emergent constraints give a value of 5.0°C whereas the three other lines of evidence are individually less tightly constrained. Nevertheless, emergent constraints are a relatively recent field of research, in part taken into account by adding uncertainty to the upper bound (Section 7.5.4.3), and the underlying studies use, to a varying extent, information that is also used in the other three lines of evidence causing statistical dependencies. However, omitting emergent constraints and statistically combining the remaining lines of evidence likewise yields 95th percentiles close to 5.0°C (Sherwood et al., 2020b). Information for the *likely* range is partly missing or one-sided, however it must necessarily reside inside the *very likely* range and is therefore supported by evidence pertaining to both the *likely* and *very likely* ranges. Hence, the upper *likely* bound is assessed to be about halfway between the best estimate and the upper *very likely* bound while the lower *likely* bound is assessed to be about halfway between the best estimate and the lower *very likely* bound. In summary, based on multiple lines of evidence the best estimate of ECS is 3°C, it is *likely* within the range 2.5 to 4°C and *very likely* within the range 2 to 5°C. It is *virtually certain* that ECS is larger than 1.5°C. Whereas there is *high confidence* based on mounting evidence that supports the best estimate, *likely* range and *very likely* lower end, a higher ECS than 5°C cannot be ruled out, hence there is *medium confidence* in the upper end of the *very likely* range. Note that the best estimate of ECS made here corresponds to a feedback parameter of –1.3 W m^{-2} $°C^{-1}$ which is slightly more negative than the feedback parameter from process based evidence alone that is assessed in Section 7.4.2.7).

There has long been a consensus (Charney et al., 1979) supporting an ECS estimates of 1.5 to 4°C. In this regard it is worth remembering the many debates challenging an ECS of this magnitude. These started as early as Ångström (1900) criticizing the results of Arrhenius (1896) arguing that the atmosphere was already saturated in infrared absorption such that adding more CO_2 would not lead to warming. The assertion of Ångström was understood half a century later to be incorrect. History has seen a multitude of studies (e.g.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Svensmark, 1998; Lindzen et al., 2001; Schwartz, 2007) mostly implying lower ECS than the range assessed as *very likely* here. However, there are also examples of the opposite such as very large ECS estimates based on the Pleistocene records (Snyder, 2016), which has been shown to be overestimated due to a lack of accounting for orbital forcing and long term ice sheet feedbacks (Schmidt et al., 2017b), or suggestions that global climate instabilities may occur in the future (Steffen et al., 2018; Schneider et al., 2019). There is, however, no evidence for unforced instabilities of such magnitude occurring in the paleo record temperatures of the past 65 million years (Westerhold et al., 2020), possibly short of the PETM excursion (Chapter 5, Section 5.3.1.1) that occurred at more than 10°C above present (Anagnostou et al., 2020). Looking back, the resulting debates have led to a deeper understanding, strengthened the consensus, and have been scientifically valuable.

In the climate sciences, there are often good reasons to consider representing deep uncertainty, or what is sometimes referred to as unknown unknowns. This is natural in a field that considers a system that is both complex and at the same time challenging to observe. For instance, since emergent constraints represent a relatively new line of evidence, important feedback mechanisms may be biased in process-level understanding, pattern effects and aerosol cooling may be large and paleo evidence inherently builds on indirect and incomplete evidence of past climate states, there certainly can be valid reasons to add uncertainty to the ranges assessed on individual lines of evidence. This has indeed been addressed throughout Sections 7.5.1–7.5.4. Since it is neither probable that all lines of evidence assessed here are collectively biased nor is the assessment sensitive to single lines of evidence, deep uncertainty it is not considered as necessary to frame the combined assessment of ECS.

[START TABLE 7.13 HERE]

Table 7.13: Summary of ECS assessment

Equilibrium Climate Sensitivity (ECS)	Central value	*Likely*	*Very likely*	*Extremely likely*
Process understanding (7.5.1)	3.4°C	2.5 to 5.1 °C	2.1 to 7.7 °C	
Warming over instrumental record (7.5.2)	2.5 to 3.5 °C	> 2.2°C	> 1.8 °C	> 1.6 °C
Paleoclimates (7.5.3)	3.3 to 3.4°C	< 4.5 °C	> 1.5°C	< 8 °C
Emergent constraints (7.5.4)	2.4 to 3.3°C		1.5 to 5.0 °C	
Combined assessment	3°C	2.5 to 4.0 °C	2.0 to 5.0 °C	

[END TABLE 7.13 HERE]

The evidence for TCR is less abundant than for ECS, and focuses on the instrumental temperature record (Sections 7.5.2 and 7.5.6), emergent constraints (Section 7.5.4.3) and process understanding (Section 7.5.1). AR5 assessed a *likely* range of 1.0 to 2.5°C. TCR and ECS are related, though, and in any case TCR is less than ECS (see Section 7.5 introduction). Furthermore, estimates of TCR from the historical record are not as strongly influenced by externally forced surface temperature pattern effects as estimates of ECS are since both historical transient warming and TCR are affected by this phenomenon (Section 7.4.4). A slightly higher weight is given to instrumental record warming and emergent constraints since these are based on observed transient warming, whereas the process understanding estimate relies on pattern effects and ocean heat uptake efficiency from ESMs to represent the transient dampening effects of the ocean. If these effects are underestimated by ESMs then the resulting TCR would be lower. Given the interdependencies of the other two lines of evidence, a conservative approach to combining them as reflected in the assessment is adopted. Since uncertainty is substantially lower than in AR5 a 0.1°C precision is therefore used here. Otherwise the same methodology for combining the lines of evidence as applied to ECS is used for TCR. Based on process understanding, warming over the instrumental record and emergent constraints the best

ACCEPTED VERSION SUBJECT TO FINAL EDITING

estimate TCR is 1.8°C, it is *likely* 1.4 to 2.2°C and *very likely* 1.2 to 2.4°C. The assessed ranges are all assigned *high confidence* due to the high level of agreement among the lines of evidence.

[START TABLE 7.14 HERE]

Table 7.14: Summary of TCR assessment

Transient Climate Response (TCR)	Central value	*Likely* range	*Very likely* range
Process understanding (7.5.1)	2.0 °C	1.6 to 2.7 °C	1.3 to 3.1 °C
Warming over instrumental record (7.5.2)	1.9 °C	1.5 to 2.3°C	1.3 to 2.7 °C
Emergent constraints (7.5.4)	1.7 °C		1.1 to 2.3°C
Combined assessment	1.8 °C	1.4 to 2.2°C	1.2 to 2.4°C

[END TABLE 7.14 HERE]

7.5.6 Considerations on the ECS and TCR in global climate models and their role in the assessment

Coupled climate models, such as those participating in CMIP, have long played a central role in assessments of ECS and TCR. In reports up to and including TAR, climate sensitivities derived directly from ESMs were the primary line of evidence. However, since AR4, historical warming and paleoclimate information provided useful additional evidence and it was noted that assessments based on models alone were problematic (Knutti, 2010). As new lines of evidence have evolved, in AR6 various numerical models are used where they are considered accurate, or in some cases the only available source of information, and thereby support all four lines of evidence (Sections 7.5.1-7.5.4). However, AR6 differs from previous IPCC reports in excluding direct estimates of ECS and TCR from ESMs in the assessed ranges (Section 7.5.5), following several recent studies (Annan and Hargreaves, 2006; Stevens et al., 2016; Sherwood et al., 2020b). The purpose of this section is to explain why this approach has been taken and to provide a perspective on the interpretation of the climate sensitivities exhibited in CMIP6 models.

The primary consideration that led to excluding ECS and TCR directly derived from ESMs is that information from these models is incorporated in the lines of evidence used in the assessment: ESMs are partly used to estimate historical- and paleoclimate ERFs (Sections 7.5.2 and 7.5.3); to convert from local to global mean paleo temperatures (Section 7.5.3), to estimate how feedbacks change with SST patterns (Section 7.4.4.3); and to establish emergent constraints on ECS (Section 7.5.4). They are also used as important evidence in the process understanding estimates of the temperature, water vapour, albedo, biogeophysical, and non-CO_2 biogeochemical feedbacks, whereas other evidence is primarily used for cloud feedbacks where the climate model evidence is weak (Section 7.4.2). One perspective on this is that the process understanding line of evidence builds on and replaces ESM estimates.

The ECS of a model is the net result of the model's effective radiative forcing from a doubling of CO_2 and the sum of the individual feedbacks and their interactions. It is well known that most of the model spread in ECS arises from cloud feedbacks, and particularly the response of low-level clouds (Bony and Dufresne, 2005; Zelinka et al., 2020). Since these clouds are small-scale and shallow, their representation in climate models is mostly determined by sub-grid scale parameterizations. It is sometimes assumed that parameterization improvements will eventually lead to convergence in model response and therefore a decrease in the model spread of ECS. However, despite decades of model development, increases in model resolution and advances in parametrization schemes, there has been no systematic convergence in model

ACCEPTED VERSION SUBJECT TO FINAL EDITING

estimates of ECS. In fact, the overall inter model spread in ECS for CMIP6 is larger than for CMIP5; ECS and TCR values are given for CMIP6 models in Supplementary Material 7.SM.4 based on Schlund et al. (2020) for ECS and Meehl et al. (2020) for TCR, see also Figure 7.18 and FAQ 7.3. The upward shift does not apply to all models traceable to specific modelling centres, but a substantial subset of models have seen an increase in ECS between the two model generations. The increased ECS values, as discussed in Section 7.4.2.8, are partly due to shortwave cloud feedbacks (Flynn and Mauritsen, 2020) and it appears that in some models extra-tropical clouds with mixed ice and liquid phases are central to the behaviour (Zelinka et al., 2020), probably borne out of a recent focus on biases in these types of clouds (McCoy et al., 2016; Tan et al., 2016). These biases have recently been reduced in many ESMs, guided by process understanding from laboratory experiments, field measurements, and satellite observations (Lohmann and Neubauer, 2018; Bodas-Salcedo et al., 2019; Gettelman et al., 2019). However, this and other known model biases are already factored into the process-level assessment of cloud feedback (Section 7.4.2.4), and furthermore the emergent constraints used here focus on global surface temperature change, which are less susceptible to shared model biases in individual feedback parameters than emergent constraints that focus on specific physical processes (Section 7.5.4). The high values of ECS and TCR in some CMIP6 models lead to higher levels of surface warming than CMIP5 simulations and also the AR6 projections based on the assessed ranges of ECS, TCR and ERF (Chapter 4, Box 4.1; FAQ 7.3; Forster et al., 2019).

It is generally difficult to determine which information enters the formulation and development of parameterizations used in ESMs. Climate models frequently share code components and in some cases entire sub-model systems are shared and slightly modified. Therefore, models cannot be considered independent developments, but rather families of models with interdependencies (Knutti et al., 2013). It is therefore difficult to interpret the collection of models (Knutti, 2010), and it cannot be ruled out that there are common limitations and therefore systematic biases to model ensembles that are reflected in the distribution of ECS as derived from them. Although ESMs are typically well-documented, in ways that increasingly include information on critical decisions regarding tuning (Mauritsen et al., 2012; Hourdin et al., 2017; Schmidt et al., 2017a; Mauritsen and Roeckner, 2020), the full history of development decisions could involve both process-understanding and sometimes also other information such as historical warming. As outlying or poorly performing models emerge from the development process, they can become re-tuned, reconfigured or discarded and so might not see publication (Hourdin et al., 2017; Mauritsen and Roeckner, 2020). In the process of addressing such issues, modelling groups may, whether intentional or not, modify the modelled ECS.

[START FIGURE 7.19 HERE]

Figure 7.19: Global mean temperature anomaly in models and observations from 5 time periods. (a) Historical (CMIP6 models), (b) post 1975 (CMIP6 models), (c) Last Glacial Maximum (LGM; Cross-Chapter Box 2.1; PMIP4 models; (Kageyama et al., 2021; Zhu et al., 2021), (d) mid Pliocene warm period (MPWP; Cross-Chapter Box 2.4; PlioMIP models; Haywood et al., 2020; Zhang et al., 2021), (e) early Eocene climatic optimum (EECO; Cross-Chapter Box 2.1; DeepMIP models; Zhu et al., 2020; Lunt et al., 2021). Grey circles show models with ECS in the assessed *very likely* range; models in red have an ECS greater than the assessed *very likely* range (>5°C), models in blue have an ECS lower than the assessed *very likely* range (<2°C). Black ranges show the assessed temperature anomaly derived from observations (Chapter 2, Section 2.3). The Historical anomaly in models and observations is calculated as the difference between 2005–2014 and 1850–1900, and the post 1975 anomaly is calculated as the difference between 2005–2014 and 1975–1984. For the LGM, MPWP, and EECO, temperature anomalies are compared with pre-industrial (equivalent to CMIP6 simulation *piControl*). All model simulations of the MPWP and LGM were carried out with atmospheric CO_2 concentrations of 400 and 190 ppm respectively. However, CO_2 during the EECO is relatively more uncertain, and model simulations were carried out at either 1120ppm or 1680 ppm (except for the one high-ECS EECO simulation which was carried out at 560 ppm; Zhu et al., 2020). The one low-ECS EECO simulation was carried out at 1680 ppm. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.19 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

It is problematic and not obviously constructive to provide weights for, or rule out, individual CMIP6 model ensemble members based solely on their ECS and TCR values. Rather these models must be tested in a like-with-like way against observational evidence. Based on the currently published CMIP6 models we provide such an analysis, marking models with ECS above and below the assessed *very likely* range (Figure 7.19). In the long term historical warming (Figure 7.19a) both low and high ECS models are able to match the observed warming, presumably in part as a result of compensating aerosol cooling (Kiehl, 2007; Forster et al., 2013; Wang et al., 2021). In several cases of high ECS models that apply strong aerosol cooling it is found to result in surface warming and ocean heat uptake evolutions that are inconsistent with observations (Golaz et al., 2019b; Andrews et al., 2020; Winton et al., 2020). Modelled warming since the 1970s is less influenced by compensation between climate sensitivity and aerosol cooling (Jiménez-de-la-Cuesta and Mauritsen, 2019; Nijsse et al., 2020) resulting in the high ECS models in general warming more than observed, whereas low sensitivity models mostly perform better (Figure 7.19b); a result that may also have been influenced by temporary pattern effects (Sections 7.4.4 and 7.5.4). Paleoclimates are not influenced by such transient pattern effects, but are limited by structural uncertainties in the proxy-based temperature and forcing reconstructions as well as possible differences in equilibrium sea-surface temperature patterns between models and the real world (Section 7.5.4). Across the LGM, MPWP and EECO (Figure 7.19c-e), the few high ECS models that simulated these cases were outside the observed *very likely* ranges; see also (Feng et al., 2020; Renoult et al., 2020; Zhu et al., 2020). Also the low ECS model is either outside or on the edge of the observed *very likely* ranges.

As a result of the above considerations, in this Report projections of global surface temperature are produced using climate model emulators that are constrained by the assessments of ECS, TCR and ERF. In reports up to and including AR5, ESM values of ECS did not fully encompass the assessed *very likely* range of ECS, raising the possibility that past multi-model ensembles underestimated the uncertainty in climate change projections that existed at the times of those reports (e.g., Knutti, 2010). However, due to an increase in the modelled ECS spread and a decrease in the assessed ECS spread based on improved knowledge in multiple lines of evidence, the CMIP6 ensemble encompasses the *very likely* range of ECS (2–5°C) assessed in Section 7.5.5. Models outside of this range are useful for establishing emergent constraints on ECS and TCR and provide useful examples of "tail risk" (Sutton, 2018), producing dynamically consistent realisations of future climate change to inform impacts studies and risk assessments.

In summary, the distribution of CMIP6 models have higher average ECS and TCR values than the CMIP5 generation of models and the assessed values of ECS and TCR in Section 7.5.5. The high ECS and TCR values can in some CMIP6 models be traced to improved representation of extra-tropical cloud feedbacks (*medium confidence*). The ranges of ECS and TCR from the CMIP6 models are not considered robust samples of possible values and the models are not considered a separate line of evidence for ECS and TCR. Solely based on its ECS or TCR values an individual ESM cannot be ruled out as implausible, though some models with high (greater than 5°C) and low (less than 2°C) ECS are less consistent with past climate change (*high confidence*). High model climate sensitivity leads to generally higher projected warming in CMIP6 compared to both CMIP5 and that assessed based on multiple lines of evidence (Chapter 4, Sections 4.3.1 and 4.3.4; FAQ 7.3).

7.5.7 Processes underlying uncertainty in the global temperature response to forcing

While the magnitude of global warming by the end of the 21st century is dominated by future greenhouse gas emissions, the uncertainty in warming for a given ERF change is dominated by the uncertainty in ECS and TCR (Chapter 4, Section 4.3.4). The proportion of variation explained by ECS and TCR varies with scenario and the time period considered, but within CMIP5 models around 60% to 90% of the globally averaged projected surface warming range in 2100 can be explained by the model range of these metrics (Grose et al., 2018). Uncertainty in the long-term global surface temperature change can further be understood in terms of the processes affecting the global TOA energy budget, namely the ERF, the radiative feedbacks which govern the efficiency of radiative energy loss to space with surface warming, and the increase in the global energy inventory (dominated by ocean heat uptake) which reduces the transient surface warming. A variety

ACCEPTED VERSION SUBJECT TO FINAL EDITING

of studies evaluate the effect of each of these processes on surface changes within coupled ESM simulations by diagnosing so-called 'warming contributions' (Dufresne and Bony, 2008; Crook et al., 2011; Feldl and Roe, 2013; Vial et al., 2013; Pithan and Mauritsen, 2014; Goosse et al., 2018). By construction, the individual warming contributions sum to the total global surface warming (Figure 7.19b). For long-term warming in response to CO_2 forcing in CMIP5 models, the energy added to the climate system by radiative feedbacks is larger than the ERF of CO_2 (Figure 7.19a), implying that feedbacks more than double the magnitude of global warming (Figure 7.19b). Radiative kernel methods (see Section 7.4.1) can be used to decompose the net energy input from radiative feedbacks into its components. The water-vapour, cloud and surface-albedo feedbacks enhance global warming, while the lapse-rate feedback reduces global warming. Ocean heat uptake reduces the rate of global surface warming by sequestering heat at depth away from the ocean surface. Section 7.4.4.1 shows the warming contributions from these factors at the regional scale.

[START FIGURE 7.20 HERE]

Figure 7.20: Contributions of effective radiative forcing, ocean heat uptake and radiative feedbacks to global atmospheric energy input and near-surface air temperature change at year 100 of *abrupt4xCO2* simulations of CMIP6 models. (a) The energy flux to the global atmosphere associated with the effective CO_2 forcing, global ocean heat uptake, Planck response, and radiative feedbacks, which together sum to zero. The inset shows energy input from individual feedbacks, summing to the total feedback energy input. (b) Contributions to net global warming are calculated by dividing the energy inputs by the *magnitude* of the global Planck response (3.2 W m^{-2} $°C^{-1}$), with the contributions from radiative forcing, ocean heat uptake, and radiative feedbacks (orange bars) summing to the value of net warming (grey bar). The inset shows warming contributions associated with individual feedbacks, summing to the total feedback contribution. Uncertainties show the interquartile range (25% and 75% percentiles) across models. Radiative kernel methods (see Section 7.4.1) were used to decompose the net energy input from radiative feedbacks into contributions from changes in atmospheric water vapour, lapse-rate, clouds, and surface albedo (Zelinka et al. (2020) using the Huang et al. (2017) radiative kernel). The CMIP6 models included are those analysed by Zelinka et al. (2020) and the warming contribution analysis is based on that of Goosse et al. (2018). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.20 HERE]

Differences in projected transient global warming across ESMs are dominated by differences in their radiative feedbacks, while differences in ocean heat uptake and radiative forcing play secondary roles (Figure 7.20b; Vial et al., 2013). The uncertainty in projected global surface temperature change associated with inter-model differences in cloud feedbacks is the largest source of uncertainty in CMIP5 and CMIP6 models (Figure 7.20b), just as they were for CMIP3 models (Dufresne and Bony, 2008). Extending this energy budget analysis to equilibrium surface warming suggests that about 70% of the inter-model differences in ECS arises from uncertainty in cloud feedbacks, with the largest contribution to that spread coming from shortwave low-cloud feedbacks (Vial et al., 2013; Zelinka et al., 2020).

Interactions between different feedbacks within the coupled climate system pose a challenge to our ability to understand global warming and its uncertainty based on energy budget diagnostics (Section 7.4.2). For example, water-vapour and lapse-rate feedbacks are correlated (Held and Soden, 2006) owing to their joint dependence on the spatial pattern of warming (Po-Chedley et al., 2018a). Moreover, feedbacks are not independent of ocean heat uptake because the uptake and transport of heat by the ocean influences the SST pattern on which global feedbacks depend (Section 7.4.4.3). However, alternative decompositions of warming contributions that better account for correlations between feedbacks produce similar results (Caldwell et al., 2016). The key role of radiative feedbacks in governing the magnitude of global warming is also supported by the high correlation between radiative feedbacks (or ECS) and transient 21st century warming within ESMs (Grose et al., 2018).

Another approach to evaluating the roles of forcing, feedbacks, and ocean heat uptake in projected warming

ACCEPTED VERSION SUBJECT TO FINAL EDITING

employs idealized energy balance models that emulate the response of ESMs, and which preserve the interactions between system components. One such emulator, used in Section 7.5.1.2, resolves the heat capacity of both the surface components of the climate system and the deep ocean (Held et al., 2010; Geoffroy et al., 2013a, 2013b; Kostov et al., 2014; Armour, 2017). Using this emulator, Geoffroy et al. (2012) find that: under an idealized 1% per year increase in atmospheric CO_2, radiative feedbacks constitute the greatest source of uncertainty (about 60% of variance) in transient warming beyond several decades; ERF uncertainty plays a secondary but important role in warming uncertainty (about 20% of variance) that diminishes beyond several decades; and ocean heat uptake processes play a minor role in warming uncertainty (less than 10% of variance) at all timescales.

More computationally intensive approaches evaluate how the climate response depends on perturbations to key parameter or structural choices within ESMs. Large 'perturbed parameter ensembles' wherein a range of parameter settings associated with cloud physics are explored within atmospheric ESMs produce a wide range of ECS due to changes in cloud feedbacks, but often produce unrealistic climate states (Joshi et al., 2010). Rowlands et al. (2012) generated a ESM perturbed-physics ensemble of several thousand members by perturbing model parameters associated with radiative forcing, cloud feedbacks, and ocean vertical diffusivity (an important parameter for ocean heat uptake). After constraining the ensemble to have a reasonable climatology and to match the observed historical surface warming, they found a wide range of projected warming by the year 2050 under the SRES A1B scenario (1.4–3°C relative to the 1961–1990 average) that is dominated by differences in cloud feedbacks. The finding that cloud feedbacks are the largest source of spread in the net radiative feedback has since been confirmed in perturbed parameter ensemble studies using several different ESMs (Gettelman et al., 2012; Tomassini et al., 2015; Kamae et al., 2016; Rostron et al., 2020; Tsushima et al., 2020). By swapping out different versions of the atmospheric or oceanic components in a coupled ESM, Winton et al. (2013) found that TCR and ECS depend on which atmospheric component was used (using two versions with different atmospheric physics), but that only TCR is sensitive to which oceanic component of the model was used (using two versions with different vertical coordinate systems, among other differences); TCR and ECS changed by 0.4°C and 1.4°C, respectively, when the atmospheric model component was changed, while TCR and ECS changed by 0.3°C and less than 0.05°C, respectively, when the oceanic model component was changed. By perturbing ocean vertical diffusivities over a wide range, Watanabe et al. (2020b) found that TCR changed by 0.16°C within the model MIROC5.2 while Krasting et al. (2018) found that ECS changed by about 0.6°C within the model GFDL-ESM2G, with this difference linked to different radiative feedbacks associated with different spatial patterns of sea-surface warming (see Section 7.4.4.3). By comparing simulations of CMIP6 models with and without the effects of CO_2 on vegetation, (Zarakas et al., 2020) find a physiological contribution to TCR of 0.12°C (range 0.02–0.29°C across models) owing to physiological adjustments to the CO_2 ERF (Section 7.3.2.1).

There is *robust evidence* and *high agreement* across a diverse range of modelling approaches and thus *high confidence* that radiative feedbacks are the largest source of uncertainty in projected global warming out to 2100 under increasing or stable emissions scenarios, and that cloud feedbacks in particular are the dominant source of that uncertainty. Uncertainty in radiative forcing plays an important but generally secondary role. Uncertainty in global ocean heat uptake plays a lesser role in global warming uncertainty, but ocean circulation could play an important role through its effect on sea-surface warming patterns which in turn project onto radiative feedbacks through the pattern effect (Section 7.4.4.3).

The spread in historical surface warming across CMIP5 ESMs shows a weak correlation with inter-model differences in radiative feedback or ocean heat uptake processes but a high correlation with inter-model differences in radiative forcing owing to large variations in aerosol forcing across models (Forster et al., 2013). Likewise, the spread in projected 21st century warming across ESMs depends strongly on emissions scenario (Hawkins and Sutton, 2012; Chapter 4, Section 4.3.1). Strong emissions reductions would remove aerosol forcing (Chapter 6, Section 6.7.2) and this could dominate the uncertainty in near-term warming projections (Armour and Roe, 2011; Mauritsen and Pincus, 2017; Schwartz, 2018; Smith et al., 2019). On post 2100 timescales carbon cycle uncertainty such as that related to permafrost thawing could become increasingly important, especially under high emission scenarios (Chapter 5, Figure 5.30).

In summary, there is *high confidence* that cloud feedbacks are the dominant source of uncertainty for late 21st

ACCEPTED VERSION SUBJECT TO FINAL EDITING

century projections of transient global warming under increasing or stable emissions scenarios, whereas uncertainty is dominated by aerosol ERF in strong mitigation scenarios. Global ocean heat uptake is a smaller source of uncertainty in long-term surface warming. (*high confidence*).

7.6 Metrics to evaluate emissions

Emission metrics are used to compare the relative effect of emissions of different gases over time in terms of radiative forcing, global surface temperature or other climate effects. They are introduced in Chapter 1, Box 1.3. Chapter 8 of AR5 (Myhre et al., 2013b) comprehensively discussed different emission metrics so this section focuses on updates since that report. Section 7.6.1 updates the physical assessment. Section 7.6.2 assesses developments in the comparison of emissions of short- and long-lived gases. Box 7.3 assesses physical aspects of emission metric use within climate policy.

7.6.1 Physical description of metrics

This section discusses metrics that relate emissions to physical changes in the climate system. Other metrics, for instance relating to economic costs or 'damage' are discussed in WG III Chapter 2. The same Chapter also assesses literature examining to what extent different physical metrics are linked to cost-benefit and cost-effectiveness metrics. One metric, the 100-year Global Warming Potential (GWP-100), has extensively been employed in climate policy to report emissions of different greenhouse gases on the same scale. Other physical metrics exist, which are discussed in this section.

Emission metrics can be quantified as the magnitude of the effect a unit mass of emission of a species has on a key measure of climate change. This section focuses on physical measures such as the radiative forcing, GSAT change, global average precipitation change, and global mean sea level rise (Myhre et al., 2013b; Sterner et al., 2014; Shine et al., 2015). When used to represent a climate effect, the metrics are referred to as absolute metrics and expressed in units of effect per kg (e.g., Absolute Global Warming Potential, AGWP or Absolute Global Temperature-change Potential, AGTP). More commonly, these are compared with a reference species (almost always CO_2 in kg(CO_2)), to give a dimensionless factor (written as e.g., Global Warming Potential (GWP) or Global Temperature-change Potential (GTP)). The unit mass is usually taken as a 1 kg instantaneous "pulse" (Myhre et al., 2013b), but can also refer to a "step" in emission rate of 1 kg yr^{-1}.

There is a cause-effect chain that links human activity to emissions, then from emissions to radiative forcing, climate response, and climate impacts (Fuglestvedt et al., 2003). Each step in the causal chain requires an inference or modelling framework that maps causes to effects. Emission metrics map from emissions of some compound to somewhere further down the cause and effect chain, radiative forcing (e.g., GWP) or temperature (e.g., GTP) or other effects (such as sea-level rise or socioeconomic impacts). While variables later in the chain have greater policy or societal relevance, they are also subject to greater uncertainty because each step in the chain includes more modelling systems, each of which brings its own uncertainty (Balcombe et al., 2018; Chapter 1, Figure 1.15).

Since AR5, understanding of the radiative effects of emitted compounds has continued to evolve and these changes are assessed in Section 7.6.1.1. Metrics relating to precipitation and sea level have also been quantified (Section 7.6.1.2). Understanding of how the carbon-cycle response to temperature effects emission metrics has improved. This allows the carbon cycle response to temperature to be more fully included in the emission metrics presented here (Section 7.6.1.3). There have also been developments in approaches for comparing short-lived greenhouse gases to CO_2 in the context of mitigation and global surface temperature change (Section 7.6.1.4). Emission metrics for selected key compounds are presented in Section 7.6.1.5.

7.6.1.1 Radiative properties and lifetimes.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The radiative properties and lifetimes of compounds are the fundamental component of all emission metrics. Since AR5, there have been advances in the understanding of the radiative properties of various compounds (see Sections 7.3.1, 7.3.2 and 7.3.3), and hence their effective radiative efficiencies (ERFs per unit change in concentration). For CO_2, CH_4 and N_2O, better accounting of the spectral properties of these gases has led to re-evaluation of their SARF radiative efficiencies and their dependence on the background gas concentrations (Section 7.3.2). For CO_2, CH_4, N_2O, CFC-11 and CFC-12 the tropospheric adjustments (Sections 7.3.1 and 7.3.2) are assessed to make a non-zero contribution to ERF. There is insufficient evidence to include tropospheric adjustments for other halogenated compounds. The re-evaluated effective radiative efficiency for CO_2 will affect all emission metrics relative to CO_2.

The effective radiative efficiencies (including adjustments from Section 7.3.2) for 2019 background concentrations for CO_2, CH_4 and N_2O are assessed to be 1.36×10^{-5}, 3.77×10^{-4} and 3.11×10^{-3} W m^{-2} ppb^{-1} respectively (see Table 7.15 for uncertainties), compared to AR5 assessments of 1.37×10^{-5}, 3.63×10^{-4} and 3.00×10^{-3} W m^{-2} ppb^{-1}. For CO_2, increases due to the re-evaluated radiative properties and adjustments balance the decreases due to the increasing background concentration. For CH_4, increases due to the re-evaluated radiative properties more than offset the decreases due to the increasing background concentration. For N_2O the addition of tropospheric adjustments increases the effective radiative efficiency. Radiative efficiencies of halogenated species have been revised slightly (Section 7.3.2.4) and for CFCs include tropospheric adjustments.

The perturbation lifetimes of CH_4 (Chapter 6, Section 6.3.1). and N_2O (Chapter 5, Section 5.2.3.1) have been slightly revised since AR5 to be 11.8 ± 1.8 years and 109 ± 10 years (Table 7.15). The lifetimes of halogenated compounds have also been slightly revised (Hodnebrog et al., 2020a).

Although there has been greater understanding since AR5 of the carbon cycle responses to CO_2 emissions (Chapter 5, Sections 5.4 and 5.5), there has been no new quantification of the response of the carbon-cycle to an instantaneous pulse of CO_2 emission since Joos et al. (2013).

7.6.1.2 Physical indicators

The basis of all the emission metrics is the time profile of effective radiative forcing (ERF) following the emission of a particular compound. The emission metrics are then built up by relating the forcing to the desired physical indicators. These forcing-response relationships can either be generated from emulators (Tanaka et al., 2013; Gasser et al., 2017b; Cross-Chapter Box 7.1), or from analytical expressions based on parametric equations (response functions) derived from more complex models (Myhre et al., 2013b).

To illustrate the analytical approach, the ERF time evolution following a pulse of emission can be considered an Absolute Global Forcing Potential AGFP (similar to the Instantaneous Climate Impact of Edwards and Trancik (2014)). This can be transformed into an Absolute Global Temperature Potential (AGTP) by combining the radiative forcing with a global surface temperature response function. This temperature response is typically derived from a two-layer energy balance emulator (Supplementary Material 7.SM.5; Myhre et al., 2013b). For further physical indicators further response functions are needed based on the radiative forcing or temperature, for instance. Sterner et al. (2014) used an upwelling-diffusion energy balance model to derive the thermosteric component of sea level rise (SLR) as response functions to radiative forcing or global surface temperature. A metric for precipitation combines both the radiative forcing (AGFP) and temperature (AGTP) responses to derive an Absolute Global Precipitation Potential AGPP (Shine et al., 2015). The equations relating these metrics are given in the Supplementary Material 7.SM.5.

The physical emission metrics described above are functions of time since typically the physical effects reach a peak and then decrease in the period after a pulse emission as the concentrations of the emitted compound decay. The value of the metrics can therefore be strongly dependent on the time horizon of interest. All relative metrics (GWP, GTP etc) are also affected by the time dependence of the CO_2 metrics in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the denominator. Instantaneous or endpoint metrics quantify the change (in radiative forcing, global surface temperature, global mean sea level) at a particular time after the emission. These can be appropriate when the goal is to not exceed a fixed target such as a temperature or global mean sea-level rise level at a specific time. Emission metrics can also be integrated from the time of emission. The most common of these is the Absolute Global Warming Potential (AGWP), which is the integral of the AGFP. The physical effect is then in units of forcing-years, degree-years or metre-years for forcing, temperature, or sea-level rise, respectively. These can be appropriate for trying to reduce the overall damage potential when the effect depends on how long the change occurs for, not just how large the change is. The integrated metrics still depend on the time horizon, though for the shorter-lived compounds this dependence is somewhat smoothed by the integration. The integrated version of a metric is often denoted as iAGxx, although the integral of the forcing-based metric (iAGFP) is known as the AGWP. Both the endpoint and integrated absolute metrics for non-CO_2 species can be divided by the equivalent for CO_2 to give relative emission metrics (e.g., GWP (=iGFP), GTP, iGTP).

Each step from radiative forcing to global surface temperature to SLR introduces longer timescales and therefore prolongs further the contributions to climate change of short-lived greenhouse gases (Myhre et al., 2013b). Thus, short-lived greenhouse gases become more important (relative to CO_2) for SLR than for temperature or radiative forcing (Zickfeld et al., 2017). Integrated metrics include the effects of a pulse emission from the time of emission up to the time horizon, whereas endpoint metrics only include the effects that persist out to the time horizon. Because the largest effects of short-lived greenhouse gases occur shortly after their emission and decline towards the end of the time period, short-lived greenhouse gases have relatively higher integrated metrics than their corresponding endpoint metrics (Peters et al., 2011; Levasseur et al., 2016).

For species perturbations that lead to a strong regional variation in forcing pattern, the regional temperature response can be different to that for CO_2. Regional equivalents to the global metrics can be derived by replacing the global surface temperature response function with a regional response matrix relating forcing changes in one region to temperature changes in another (Collins et al., 2013b; Aamaas et al., 2017; Lund et al., 2017).

For the research discussed above, metrics for several physical variables can be constructed that are linear functions of radiative forcing. Similar metrics could be devised for other climate variables provided they can be related by response functions to radiative forcing or global surface temperature change. The radiative forcing does not increase linearly with emissions for any species, but the non-linearities (for instance changes in CO_2 radiative efficiency) are small compared to other uncertainties.

7.6.1.3 Carbon cycle responses and other indirect contributions

The effect of a compound on climate is not limited to its direct radiative forcing. Compounds can perturb the carbon cycle affecting atmospheric CO_2 concentrations. Chemical reactions from emitted compounds can produce or destroy other greenhouse gases or aerosols.

Any agent that warms the surface perturbs the terrestrial and oceanic carbon fluxes (Chapter 5, Sections 5.4.3 and 5.4.4), typically causing a net flux of CO_2 into the atmosphere and hence further warming. This aspect is already included in the carbon cycle models that are used to generate the radiative effects of a pulse of CO_2 (Joos et al., 2013), but was neglected for non-CO_2 compounds in the conventional metrics so this introduces an inconsistency and bias in the metric values (Gillett and Matthews, 2010; MacDougall et al., 2015; Tokarska et al., 2018). A simplistic account of the carbon cycle response was tentatively included in AR5 based on a single study (Collins et al., 2013b). Since AR5 this understanding has been revised (Gasser et al., 2017b; Sterner and Johansson, 2017) using simple parameterised carbon cycle models to derive the change in CO_2 surface flux for a unit temperature pulse as an impulse response function to temperature. In Collins et al. (2013a) this response function was assumed to be simply a delta function, whereas the newer studies include a more complete functional form accounting for subsequent re-uptake of CO_2 after the removal of the temperature increase. Accounting for re-uptake has the effect of reducing the carbon-cycle

ACCEPTED VERSION SUBJECT TO FINAL EDITING

responses associated with the metrics compared to AR5, particularly at large time horizons. The increase in any metric due to the carbon cycle response can be derived from the convolution of the global surface temperature response with the CO_2 flux response to temperature and the equivalent metric for CO_2 (equation 7.SM.5.5 in the Supplementary Material). Including this response also increases the duration of the effect of short-lived greenhouse gases on climate (Fu et al., 2020). An alternative way of accounting for the carbon cycle temperature response would be to incorporate it into the temperature response function (the response functions used here and given in Supplementary Material 7.SM.5.2 do not explicitly do this). If this were done, the correction could be excluded from both the CO_2 and non-CO_2 forcing responses as in Hodnebrog et al. (2020a).

Including the carbon cycle response for non-CO_2 treats CO_2 and non-CO_2 compounds consistently and therefore we assess that its inclusion more accurately represents the climate effects of non-CO_2 species. There is *high confidence* in the methodology of using carbon cycle models for calculating the carbon cycle response. The magnitude of the carbon cycle response contributions to the emission metrics vary by a factor of two between Sterner and Johansson (2017) and Gasser et al. (2017b). The central values are taken from Gasser et al. (2017b) as the OSCAR 2.2 model used is based on parameters derived from CMIP5 models, and the climate-carbon feedback magnitude is therefore similar to the CMIP5 multi-model mean (Arora et al., 2013; Lade et al., 2018). As values have only been calculated in two simple parameterised carbon cycle models the uncertainty is assessed to be ±100%. Due to few studies and a factor of two difference between them, there is *low confidence* that the magnitude of the carbon cycle response is within the higher end of this uncertainty range, but *high confidence* that the sign is positive. Carbon cycle responses are included in all the metrics presented in Tables 7.15 and Supplementary Table 7.SM.7. The carbon cycle contribution is lower than in AR5, but there is *high confidence* in the need for its inclusion and the method by which it is quantified.

Emissions of non-CO_2 species can affect the carbon cycle in other ways: emissions of ozone precursors can reduce the carbon uptake by plants (Collins et al., 2013b); emissions of reactive nitrogen species can fertilize plants and hence increase the carbon uptake (Zaehle et al., 2015); and emissions of aerosols or their precursors can affect the utilisation of light by plants (Cohan et al., 2002; Mercado et al., 2009; Mahowald et al., 2017) (see Chapter 6, Section 6.4.4 for further discussion). There is *robust evidence* that these processes occur and are important, but *insufficient evidence* to determine the magnitude of their contributions to emission metrics. Ideally, emission metrics should include all indirect effects to be consistent, but limits to our knowledge restrict how much can be included in practice.

Indirect contributions from chemical production or destruction of other greenhouse gases are quantified in Chapter 6, Section 6.4. For methane, AR5 (Myhre et al., 2013b) assessed that the contributions from effects on ozone and stratospheric water vapour add 50% ± 30% and 15% ± 11% to the emission-based ERF, which were equivalent to $1.8 \pm 0.7 \times 10^{-4}$ and $0.5 \pm 0.4 \times 10^{-4}$ W m^{-2} ppb $(CH_4)^{-1}$. In AR6 the radiative efficiency formulation is preferred as it is independent of the assumed radiative efficiency for methane. The assessed contributions to the radiative efficiency for methane due to ozone are $1.4 \pm 0.7 \times 10^{-4}$ W m^{-2} ppb $(CH_4)^{-1}$, based on 0.14 W m^{-2} forcing from a 1023 ppb (1850 to 2014) methane change (Thornhill et al., 2021b). The contribution from stratospheric water vapour is $0.4 \pm 0.4 \times 10^{-4}$ W m^{-2} ppb $(CH_4)^{-1}$, based on 0.05 W m^{-2} forcing from a 1137 ppb (1750 to 2019) methane change (Section 7.3.2.6). N_2O depletes upper stratospheric ozone (a positive forcing) and reduces the methane lifetime. In AR5 the methane lifetime effect was assessed to reduce methane concentrations by 0.36 ppb per ppb increase in N_2O, with no assessment of the effective radiative forcing from ozone. This is now increased to –1.7 ppb methane per ppb N_2O (based on a methane lifetime decrease of 4% ± 4% for a 55 ppb increase in N_2O (Thornhill et al., 2021b) and a radiative efficiency of $5.5 \pm 0.4 \times 10^{-4}$ W m^{-2} ppb $(N_2O)^{-1}$ through ozone (Thornhill et al., 2021b). In summary, GWPs and GTPs for methane and nitrous oxide are slightly lower than in AR5 (*medium confidence*) due to revisions in their lifetimes and updates to their indirect chemical effects.

Methane can also affect the oxidation pathways of aerosol formation (Shindell et al., 2009) but the available literature is insufficient to make a robust assessment of this. Hydrocarbon and molecular hydrogen oxidation also leads to tropospheric ozone production and change in methane lifetime (Collins et al., 2002; Hodnebrog et al., 2018). For reactive species the emission metrics can depend on where the emissions occur, and the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

season of emission (Aamaas et al., 2016; Lund et al., 2017; Persad and Caldeira, 2018). AR5 included a contribution to the emission metrics for ozone-depleting substances (ODSs) from the loss of stratospheric ozone. The assessment of ERFs from ODSs in Chapter 6 (Section 6.4.2) suggests the quantification of these terms may be more uncertain than the formulation in AR5 so these are not included here.

Oxidation of methane leads ultimately to the net production of atmospheric CO_2 (Boucher et al., 2009). This yield is less than 100% (on a molar basis) due to uptake by soils and some of the reaction products (mainly formaldehyde) being directly removed from the atmosphere before being completely oxidised. Estimates of the yield are 61% (Boucher et al., 2009) and 88% (Shindell et al., 2017), so the assessed range is 50-100% with a central value of 75% *(low confidence)*. For methane and hydrocarbons from fossil sources, this will lead to additional fossil CO_2 in the atmosphere whereas for biogenic sources of methane or hydrocarbons, this replaces CO_2 that has been recently removed from the atmosphere. Since the ratio of molar masses is 2.75, 1 kg of methane generates 2.1± 0.7 kg CO_2 for a 75% yield. For biogenic methane the soil uptake and removal of partially-oxidised products is equivalent to a sink of atmospheric CO_2 of 0.7 ± 0.7 kg per kg methane. The contributions of this oxidation effect to the methane metric values allow for the time delay in the oxidation of methane. Methane from fossil fuel sources has therefore slightly higher emission metric values than those from biogenic sources (*high confidence*). The CO_2 can already be included in carbon emission totals (Muñoz and Schmidt, 2016) so care needs to be taken when applying the fossil correction to avoid double counting.

7.6.1.4 Comparing long-lived with short-lived greenhouse gases

Since AR5 there have been developments in how to account for the different behaviours of short-lived and long-lived compounds. Pulse-based emission metrics for short-lived greenhouse gases with lifetimes less than twenty years are very sensitive to the choice of time horizon (e.g. Pierrehumbert, 2014). Global surface temperature changes following a pulse of CO_2 emissions are roughly constant in time (the principle behind TCRE, Figure 7.21b, Chapter 5, Section 5.5.1) whereas the temperature change following a pulse of short-lived greenhouse gas emission declines with time. In contrast to a one-off pulse, a step change in short-lived greenhouse gas emissions that is maintained indefinitely causes a concentration increase that eventually equilibrates to a steady state in a way that is more comparable to a pulse of CO_2. Similarly the resulting change in global surface temperature from a step change in short-lived greenhouse gases (Figure 7.21a) after a few decades increases only slowly (due to accumulation of heat in the deep ocean) and hence its effects are more similar to a pulse of CO_2 (Smith et al., 2012; Lauder et al., 2013; Allen et al., 2016, 2018b). The different time dependence of short-lived and long-lived compounds can be accounted for exactly with the CO_2 forcing equivalent metric (Wigley, 1998; Allen et al., 2018b; Jenkins et al., 2018) that produces a CO_2 emission time profile such that the radiative forcing matches the time evolution of that from the non-CO_2 emissions. But other metric approaches can approximate this exact approach.

The similarity in behaviour of step changes in short-lived greenhouse gas emissions and pulses of CO_2 emissions has recently been used to formulate new emissions metric concepts (Collins et al., 2020). For short-lived greenhouse gases, these new concepts use a step change in the rate of emissions, in contrast to an instantaneous pulse in a given year that is typically used (e.g. Myhre et al., 2013b). Metrics for step emission changes are denoted here by a superscript "*S*" (e.g., $AGTP_X^S$ is the absolute global surface temperature change potential from a unit step change in emissions of species "*X*"). These can be derived by integrating the more standard pulse emission changes up to the time horizon. The response to a step emission change is therefore equivalent to the integrated response to a pulse emission ($AGTP_X^S = iAGTP_X$); and the radiative forcing response to a step emission change $AGFP_X^S$ is equivalent to the integrated forcing response $iAGFP_X$which is the AGWP. The step metric for short-lived greenhouse gases can then be compared with the pulse metric for CO_2 in a ratio $AGTP_X^S/AGTP_{CO2}$ (Collins et al., 2020). This is referred to as a combined-GTP (CGTP) in Collins et al. (2020), and has units of years (the standard GTP is dimensionless). This CGTP shows less variation with time than the standard GTP (comparing Figure 7.21c with Figure 7.21d) and provides a scaling for comparing a change in emission rate (in kg yr^{-1}) of short-lived greenhouse gases with a pulse emission or change in cumulative CO_2 emissions (in kg). Cumulative CO_2 equivalent emissions are given by CGTP × emission rate of short-lived greenhouse gases. The CGTP can be

ACCEPTED VERSION SUBJECT TO FINAL EDITING

calculated for any species, but it is least dependent on the chosen time horizon for species with lifetimes less than half the time horizon of the metric (Collins et al., 2020). Pulse-step metrics can therefore be useful where time dependence of pulse metrics, like GWP or GTP, complicates their use (see Box 7.3).

For a stable global warming from non-CO_2 climate agents (gas or aerosol) their effective radiative forcing needs to gradually decrease (Tanaka and O'Neill, 2018). Cain et al. (2019) find this decrease to be around 0.3% yr^{-1} for the climate response function in AR5 (Myhre et al., 2013b). To account for this, a quantity referred to as GWP* has been defined that combines emissions (pulse) and changes in emission levels (step) approaches (Cain et al., 2019; Smith et al., 2021)[2]. The emission component accounts for the need for emissions to decrease to deliver a stable warming. The step (sometimes referred to as flow or rate) term in GWP* accounts for the change in global surface temperature that arises in from a change in short-lived greenhouse gas emission rate, as in CGTP, but here approximated by the change in emissions over the previous 20 years.

Cumulative CO_2 emissions and GWP*-based cumulative CO_2 equivalent greenhouse gas (GHG) emissions multiplied by TCRE closely approximate the global warming associated with emissions timeseries (of CO_2 and GHG, respectively) from the start of the time-series (Lynch et al., 2020). Both the CGTP and GWP* convert short-lived greenhouse gas emission rate changes into cumulative CO_2 equivalent emissions, hence scaling these by TCRE gives a direct conversion from short-lived greenhouse gas emission to global surface temperature change. By comparison expressing methane emissions as CO_2 equivalent emissions using GWP-100 overstates the effect of constant methane emissions on global surface temperature by a factor of 3-4 over a 20-year time horizon (Lynch et al., 2020, their Figure 5), while understating the effect of any new methane emission source by a factor of 4-5 over the 20 years following the introduction of the new source (Lynch et al., 2020, their Figure 4).

[START FIGURE 7.21 HERE]

Figure 7.21: Emission metrics for two short-lived greenhouse gases: HFC-32 and CH_4, (lifetimes of 5.4 and 11.8 years). The temperature response function comes from Supplementary Material 7.SM.5.2. Values for non-CO_2 species include the carbon cycle response (Section 7.6.1.3). Results for HFC-32 have been divided by 100 to show on the same scale. (a) temperature response to a step change in short-lived greenhouse gas emission. (b) temperature response to a pulse CO_2 emission. (c) conventional GTP metrics (pulse vs pulse). (d) combined-GTP metric (step versus pulse). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.21 HERE]

Figure 7.22 explores how cumulative CO_2 equivalent emissions estimated for methane vary under different emission metric choices and how estimates of the global surface air temperature (GSAT) change deduced from these cumulative emissions compare to the actual temperature response computed with the two-layer emulator. Note that GWP and GTP metrics were not designed for use under a cumulative carbon dioxide equivalent emission framework (Shine et al., 1990, 2005), even if they sometimes are (e.g. Cui et al., 2017; Howard et al., 2018) and analysing them in this way can give useful insights into their physical properties. Using these standard metrics under such frameworks, the cumulative CO_2 equivalent emission associated with methane emissions would continue to rise if methane emissions were substantially reduced but remained above zero. In reality, a decline in methane emissions to a smaller but still positive value could cause a declining warming. GSAT changes estimated with cumulative CO_2 equivalent emissions computed with GWP-20 matches the warming trend for a few decades but quickly overestimates the response. Cumulative emissions using GWP-100 perform well when emissions are increasing but not when they are stable or decreasing. Cumulative emissions using GTP-100 consistently underestimate the warming. Cumulative emissions using either CGTP or GWP* approaches can more closely match the GSAT evolution (Allen et al., 2018b; Cain et al., 2019; Collins et al., 2020; Lynch et al., 2020).

[2] To calculate CO_2 equivalent emissions under GWP*, the short-lived greenhouse gas emissions are multiplied by GWP100 × 0.28 and added to the net emission increase or decrease over the previous 20 years multiplied by GWP100 x 4.24 (Smith et al., 2021).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

In summary, new emission metric approaches such as GWP* and CGTP are designed to relate emission changes in short-lived greenhouse gases to emissions of CO_2 as they better account for the different physical behaviours of short and long-lived gases. Through scaling the corresponding cumulative CO_2 equivalent emissions by the TCRE, the GSAT response from emissions over time of an aggregated set of gases can be estimated. Using either these new approaches, or treating short and long-lived GHG emission pathways separately, can improve the quantification of the contribution of emissions to global warming within a cumulative emission framework, compared to approaches that aggregate emissions of GHGs using standard CO_2 equivalent emission metrics. As discussed in Box 7.3, there is *high confidence* that multi-gas emission pathways with the same time dependence of aggregated CO_2 equivalent emissions estimated from standard approaches, such as weighting emissions by their GWP-100 values, rarely lead to the same estimated temperature outcomes..

[START FIGURE 7.22 HERE]

Figure 7.22: Explores how cumulative carbon dioxide equivalent emissions estimated for methane vary under different emission metric choices and how estimates of the global surface air temperature (GSAT) change deduced from these cumulative emissions compare to the actual temperature response computed with the two-layer emulator (solid black lines). Panels a) and b) show the SSP4-6.0 and SSP1-2.6 scenarios respectively. The panels show annual methane emissions as the dotted lines (left axis) from 1750–2100. The solid lines can be read as either estimates of GSAT change or estimates of the cumulative carbon dioxide equivalent emissions. This is because they are related by a constant factor, the TCRE. Thus, values can be read using either of the right hand axes. Emission metric values are taken from Table 7.15. The GWP* calculation is given in Section 7.6.1.4. The two-layer emulator has been calibrated to the central values of the report's assessment (see Supplementary Material 7.SM.5.2). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.22 HERE]

7.6.1.5 Emission metrics by compounds

Emission metrics for selected compounds are presented in Table 7.15, with further compounds presented in the Supplementary Material Table 7.SM.7. The evolution of the CO_2 concentrations in response to a pulse emission is as in AR5 (Joos et al., 2013; Myhre et al., 2013b), the perturbation lifetimes for CH_4 and N_2O are from Section 7.6.1.1. The lifetimes and radiative efficiencies for halogenated compounds are taken from Hodnebrog et al. (2020a). Combined metrics (CGTPs) are presented for compounds with lifetimes less than 20 years. Note CGTP has units of years and is applied to a change in emission rate rather than a change in emission amount. Changes since AR5 are due to changes in radiative properties and lifetimes (Section 7.6.1.1), and indirect contributions (Section 7.6.1.3). Table 7.15 also gives overall emission uncertainties in the emission metrics due to uncertainties in radiative efficiencies, lifetimes and the climate response function (Supplementary Material Tables 7.SM.8 to 7.SM.13)

Following their introduction in AR5 the assessed metrics now routinely include the carbon-cycle response for non-CO_2 gases (Section 7.6.1.3). As assessed in this earlier section, the carbon cycle contribution is lower than in AR5. Contributions to CO_2 formation are included for methane depending on whether or not the source originates from fossil carbon, thus methane from fossil fuel sources has slightly higher emission metric values than that from non-fossil sources.

[START TABLE 7.15 HERE]

Table 7.15: Emission metrics for selected species: Global Warming Potential (GWP), Global Temperature-change Potential (GTP). All values include carbon cycle responses as described in Section 7.6.1.3. Combined-GTPs (CGTPs) are shown only for species with a lifetime less than 20 years (see Section 7.6.1.4). Note CGTP has units of years and is applied to a change in emission rate rather than a change in emission

ACCEPTED VERSION SUBJECT TO FINAL EDITING

amount. The radiative efficiencies are as described in Section 7.3.2 and include tropospheric adjustments where assessed to be non-zero in Section 7.6.1.1. The climate response function is from Supplementary Material 7.SM.5.2. Uncertainty calculations are presented in Supplementary Tables 7.SM.8 to 7.SM.13. Chemical effects of CH_4 and N_2O are included (Section 7.6.1.3). Contributions from stratospheric ozone depletion to halogenated species metrics are not included. Supplementary Table 7.SM.7 presents the full table.

# Species	Lifetime (years)	Radiative efficiency (W m^{-2} ppb^{-1})	GWP-20	GWP-100	GWP-500	GTP-50	GTP-100	CGTP-50 (years)	CGTP-100 (years)
CO2	Multiple	$1.33\pm0.16 \times 10^{-5}$	1.	1.000	1.000	1.000	1.000		
CH_4-fossil	11.8 ±1.8	$5.7\pm1.4\times10^{-4}$	82.5 ±25.8	29.8 ±11	10.0 ±3.8	13.2 ±6.1	7.5 ±2.9	2823 ±1060	3531 ±1385

[END TABLE 7.15 HERE]

[START BOX 7.3 HERE]

BOX 7.3: Physical considerations in emission-metric choice

Following AR5, this report does not recommend an emission metric because the appropriateness of the choice depends on the purposes for which gases or forcing agents are being compared. Emission metrics can facilitate the comparison of effects of emissions in support of policy goals. They do not define policy goals or targets but can support the evaluation and implementation of choices within multi-component policies (e.g., they can help prioritise which emissions to abate). The choice of metric will depend on which aspects of climate change are most important to a particular application or stakeholder and over which time-horizons. Different international and national climate policy goals may lead to different conclusions about what is the most suitable emission metric (Myhre et al., 2013b).

GWP and GTP give the relative effect of pulse emissions, i.e. how much more energy is trapped (GWP) or how much warmer (GTP) the climate would be when unit emissions of different compounds are compared (Section 7.6.1.2). Consequently, these metrics provide information on how much energy accumulation (GWP) or how much global warming (GTP) could be avoided (over a given time period, or at a given future point in time) by avoiding the emission of a unit of a short-lived greenhouse gas compared to avoiding a unit of CO_2. By contrast, the new metric approaches of Combined-GTP and GWP* closely approximate the additional effect on climate from a time-series of short-lived greenhouse gas emissions, and can be used to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

compare this to the effect on temperature from the emission or removal of a unit of CO_2 (Allen et al., 2018b; Collins et al., 2020; Section 7.6.1.4).

If global surface temperature stabilization goals are considered, cumulative CO_2 equivalent emissions computed with the GWP-100 emission metric would continue to rise when short-lived greenhouse gas emissions are reduced but remain above zero (Figure 7.22b). Such as rise would not match the expected global surface temperature stabilization or potential decline in warming that comes from a reduction in emissions of short-lived greenhouse gases (Pierrehumbert, 2014; Allen et al., 2018b; Cain et al., 2019; Collins et al., 2020; Lynch et al., 2020, 2021). This is relevant to net zero greenhouse gas emission goals (See Section 7.6.2 and Chapter 1, Box 1.4).

When individual gases are treated separately in climate model emulators (Cross-Chapter Box 7.1), or weighted and aggregated using an emission metric approach (such as CGTP or GWP*) which translate the distinct behaviour from cumulative emissions of short-lived gases, ambiguity in the future warming trajectory of a given emission scenario can be substantially reduced (Cain et al., 2019; Denison et al., 2019; Collins et al., 2020; Lynch et al., 2021). The degree of ambiguity varies with the emissions scenario. For mitigation pathways that limit warming to 2°C with an even chance, the ambiguity arising from using GWP-100 as sole constraint on emissions of a mix of greenhouse gases (without considering their economic implications or feasibility) could be as much as 0.17°C, which represents about one fifth of the remaining global warming in those pathways (Denison et al., 2019). If the evolution of the individual GHGs are not known, this can make it difficult to evaluate how a given global multi-gas emission pathway specified only in CO_2 equivalent emissions would achieve (or not) global surface temperature goals. This is potentially an issue as Nationally Determined Contributions frequently make commitments in terms of GWP-100 based CO_2- equivalent emissions at 2030 without specifying individual gases (Denison et al., 2019). Clear and transparent representation of the global warming implications of future emission pathways including Nationally Determined Contributions could be achieved either by their detailing pathways for multiple gases or by detailing a pathway of cumulative carbon dioxide equivalent emission approach aggregated across greenhouse gases evaluated by either GWP* or CGTP metric approaches (Cain et al., 2019; Collins et al., 2020; Lynch et al., 2021). Note that although the Paris Agreement Rulebook asks countries to report emissions of individual greenhouse gases separately for the global stocktake (Decision 18/CMA.1, annex, paragraph 38) which can allow the current effects of their emissions on global surface temperature to be accurately estimated, estimates of future warming are potentially ambiguous where emissions are aggregated using GWP-100 or other pulse metrics.

Although there is significant history of using single-basket approaches, supported by emission metrics such as GWP-100, in climate policies such as the Kyoto Protocol, multi-basket approaches also have many precedents in environmental management, including the Montreal Protocol (Daniel et al., 2012). Further assessment of the performance of physical and economics-based metrics in the context of climate change mitigation is provided in the contribution of Working Group III to the AR6.

[END BOX 7.3 HERE]

7.6.2 Applications of emission metrics

One prominent use of emission metrics is for comparison of efforts measured against climate change goals or targets. One of the most commonly discussed goals are in Article 2 of the Paris Agreement which aims to limit the risks and impacts of climate change by setting temperature goals. In addition, the Paris Agreement has important provisions which relate to how the goals are to be achieved, including making emissions reductions in a manner that does not threaten food production (Article 2), an early emissions peaking target, and the aim to "achieve a balance between anthropogenic emissions by sources and removals by sinks of greenhouse gases in the second half of this century" (Article 4). Article 4 also contains important context regarding international equity, sustainable development, and poverty reduction. Furthermore, the United Nations Framework Convention on Climate Change (UNFCCC) sets out as its ultimate objective, the "stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous

ACCEPTED VERSION SUBJECT TO FINAL EDITING

anthropogenic interference with the climate system."

How the interpretation of the Paris Agreement and the meaning of "net zero" emissions, reflects on the appropriate choice of metric is an active area of research (Schleussner et al., 2016, 2019; Fuglestvedt et al., 2018; Collins et al., 2020). Several possible scientific interpretations of the Article 2 and 4 goals can be devised, and these along with emission metric choice have implications both for when a balance in GHG emissions, net zero CO_2 emissions or net zero GHG emissions are achieved, and for their meaning in terms of temperature outcome (Fuglestvedt et al., 2018; Rogelj et al., 2018; Wigley, 2018). In AR6 net zero greenhouse gas emissions is defined as the condition in which metric-weighted anthropogenic GHG emissions are balanced by metric-weighted anthropogenic GHG removals over a specified period (see Chapter 1, Box 1.4, Appendix VII: Glossary). The quantification of net zero GHG emissions depends on the GHG emission metric chosen to compare emissions and removals of different gases, as well as the time horizon chosen for that metric. As the choice of emission metric affects the quantification of net zero GHG emissions, it therefore affects the resulting temperature outcome after net zero emissions are achieved (Lauder et al., 2013; Rogelj et al., 2015; Fuglestvedt et al., 2018; Schleussner et al., 2019). Schleussner et al.(2019) note that declining temperatures may be a desirable outcome of net zero. Rogelj and Schleussner (2019) also point out that the physical metrics raise questions of equity and fairness between developed and developing countries.

Based on SR1.5 (Allen et al., 2018a), there is *high confidence* that achieving net zero CO_2 emissions and declining non-CO_2 radiative forcing would halt human-induced warming. Based on (Bowerman et al., 2013; Pierrehumbert, 2014; Fuglestvedt et al., 2018; Tanaka and O'Neill, 2018; Schleussner et al., 2019) there is also *high confidence* that reaching net zero GHG emissions as quantified by GWP-100 typically leads to reductions from peak global surface temperature after net zero GHGs emissions are achieved, depending on the relative sequencing of mitigation of short-lived and long-lived species. If both short- and long-lived species are mitigated together, then temperatures peak and decline. If mitigation of short-lived species occurs much earlier than that of long-lived species, then temperatures stabilise very near peak values, rather than decline. Temperature targets can be met even with positive net GHG emissions based on GWP-100 (Tanaka and O'Neill, 2018). As demonstrated by Allen et al. (2018b), Cain et al. (2019), Schleussner et al. (2019) and Collins et al. (2020) reaching net zero GHG emissions when quantified using the new emission metric approaches such as CGTP or GWP* would lead to an approximately similar temperature evolution as achieving net zero CO_2. Hence, net zero CO_2 and net zero GHG quantified using these new approaches would both lead to approximately stable contributions to temperature change after net zero emissions are achieved (*high confidence*).

Comparisons with emission or global surface temperature stabilisation goals are not the only role for emissions metrics. Other important roles include those in pricing approaches where policymakers choose to compare short-lived and long-lived climate forcers (e.g. Manne and Richels, 2001), and in life cycle analyses (e.g. Hellweg and Milà i Canals, 2014). Several papers have reviewed the issue of metric choice for life cycle analyses, noting that analysts should be aware of the challenges and value judgements inherent in attempting to aggregate the effects of forcing agents with different timescales onto a common scale (e.g. Mallapragada and Mignone, 2017) and recommend aligning metric choice with policy goals as well as testing sensitivities of results to metric choice (Cherubini et al., 2016). Furthermore, life cycle analyses approaches which are sensitive to choice of emission metric benefit from careful communication of the reasons for the sensitivity (Levasseur et al., 2016).

Frequently Asked Questions

[START FAQ7.1 HERE]

FAQ 7.1: What is the Earth's energy budget, and what does it tell us about climate change?

The Earth's energy budget describes the flow of energy within the climate system. Since at least 1970 there has been a persistent imbalance in the energy flows that has led to excess energy being absorbed by the climate system. By measuring and understanding these energy flows and the role that human activities play in changing them, we are better able to understand the causes of climate change and project future climate change more accurately.

Our planet receives vast amounts of energy every day in the form of sunlight. Around a third of the sunlight is reflected back to space by clouds, by tiny particles called *aerosols*, and by bright surfaces such as snow and ice. The rest is absorbed by the ocean, land, ice, and atmosphere. The planet then emits energy back out to space in the form of thermal radiation. In a world that was not warming or cooling, these energy flows would balance. Human activity has caused an imbalance in these energy flows.

We measure the influence of various human and natural factors on the energy flows at the top of our atmosphere in terms of *radiative forcings*, where a positive radiative forcing has a warming effect and a negative radiative forcing has a cooling effect. In response to these forcings, the Earth system will either warm or cool, so as to restore balance through changes in the amount of outgoing thermal radiation (the warmer the Earth, the more radiations it emits). Changes in Earth's temperature in turn lead to additional changes in the climate system (known as *climate feedbacks*) that either amplify or dampen the original effect. For example, Arctic sea-ice has been melting as the Earth warms, reducing the amount of reflected sunlight and adding to the initial warming (an amplifying feedback). The most uncertain of those climate feedbacks are clouds, as they respond to warming in complex ways that affect both the emission of thermal radiation and the reflection of sunlight. However, we are now more confident that cloud changes, taken together, will amplify climate warming (see FAQ 7.2).

Human activities have unbalanced these energy flows in two main ways. First, increases in greenhouse gas levels have led to more of the emitted thermal radiation being absorbed by the atmosphere, instead of being released to space. Second, increases in pollutants have increased the amount of aerosols such as sulphates in the atmosphere (see FAQ 6.1). This has led to more incoming sunlight being reflected away, by the aerosols themselves and through the formation of more cloud drops, which increases the reflectivity of clouds (see FAQ 7.2).

Altogether, the global energy flow imbalance since the 1970s has been just over half a watt per square metre of the Earth's surface. This sounds small, but because the imbalance is persistent and because Earth's surface is large, this adds up to about 25 times the total amount of primary energy consumed by human society, compared over 1971 to 2018. Compared to the IPCC Fifth Assessment Report, we are now better able to quantify and track these energy flows from multiple lines of evidence, including satellite data, direct measurements of ocean temperatures, and a wide variety of other Earth system observations (see FAQ 1.1). We also have a better understanding of the processes contributing to this imbalance, including the complex interactions between aerosols, clouds and radiation.

Research has shown that the excess energy since the 1970s has mainly gone into warming the ocean (91%), followed by the warming of land (5%) and the melting ice sheets and glaciers (3%). The atmosphere has warmed substantially since 1970, but because it is comprised of thin gases it has absorbed only 1% of the excess energy (FAQ 7.1, Figure 1). As the ocean has absorbed the vast majority of the excess energy, especially within their top two kilometres, the deep ocean is expected to continue to warm and expand for centuries to millennia, leading to long-term sea level rise – even if atmospheric greenhouse gas levels were to decline (see FAQ 5.3). This is in addition to the sea level rise expected from melting ice sheets and glaciers.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Understanding the Earth's energy budget also helps to narrow uncertainty in future projections of climate. By testing climate models against what we know about the Earth's energy budget, we can make more confident projections of surface temperature changes we might expect this century and beyond.

[START FAQ7.1, FIGURE 1 HERE]

FAQ7.1, Figure 1: The Earth's energy budget compares the flows of incoming and outgoing of energy that are relevant for the climate system. Since the at least the 1970s, less energy is flowing out than is flowing in, which leads to excess energy being absorbed by the ocean, land, ice and atmosphere, with the ocean absorbing 91%.

FAQ 7.2: Clouds – What is the role in a warming climate?

One of the biggest challenges in climate science has been to predict how clouds will change in a warming world and whether those changes will amplify or partially offset the warming caused by increasing concentrations of greenhouse gases and other human activities. Scientists have made significant progress over the past decade and are now more confident that changes in clouds will amplify, rather than offset, global warming in the future.

Clouds cover roughly two thirds of the Earth's surface. They consist of small droplets and/or ice crystals, which form when water vapour condenses or deposits around tiny particles called *aerosols* (such as salt, dust, or smoke). Clouds play a critical role in the Earth's *energy budget* at the top of atmosphere and therefore influence Earth's surface temperature (see FAQ 7.1) . The interactions between clouds and the climate are complex and varied. Clouds at low altitudes tend to reflect incoming solar energy back to space, preventing this energy from reaching and warming the Earth and causing a cooling effect. On the other hand, higher clouds tend to trap (i.e., absorb and then emit at a lower temperature) some of the energy leaving the Earth, leading to a warming effect. On average, clouds reflect back more incoming energy than the amount of outgoing energy they trap, resulting in an overall net cooling effect on the present climate. Human activities since the pre-industrial era have altered this climate effect of clouds in two different ways: by changing the abundance of the aerosol particles in the atmosphere and by warming the Earth's surface, primarily as a result of increases in greenhouse gas emissions.

The concentration of aerosols in the atmosphere has markedly increased since the pre-industrial era, and this has had two important effects on clouds. First, clouds now reflect more incoming energy because cloud droplets have become more numerous and smaller. Second, smaller droplets may delay rain formation, thereby making the clouds last longer, although this effect remains uncertain. Hence, aerosols released by human activities have had a cooling effect, counteracting a considerable portion of the warming caused by increases in greenhouse gases over the last century (see FAQ 3.1). Nevertheless, this cooling effect is expected to diminish in the future, as air pollution policies progress worldwide, reducing the amount of aerosols released into the atmosphere.

Since the pre-industrial period, the Earth's surface and atmosphere have warmed, altering the properties of clouds, such as their altitude, amount, and composition (water or ice), thereby affecting the Earth's energy budget and, in turn, changing temperature. This cascading effect of clouds, known as the *cloud feedback,* could either amplify or offset some of the future warming and has long been the biggest source of uncertainty in climate projections. The problem stems from the fact that clouds can change in many ways and that their processes occur on much smaller scales than what global climate models can explicitly represent. As a result, global climate models have disagreed on how clouds, particularly over the subtropical ocean, will change in the future and whether the change will amplify or suppress the global warming.

Since the last IPCC Report in 2013, understanding of cloud processes has advanced with better observations, new analysis approaches and explicit high-resolution numerical simulation of clouds. Also, current global climate models simulate cloud behaviour better than previous models, due both to advances in computational capabilities and process understanding. Altogether, this has helped to build a more complete picture of how clouds will change as the climate warms (FAQ 7.2, Figure 1). For example, the amount of low clouds will reduce over the subtropical ocean, leading to less reflection of incoming solar energy, and the altitude of high clouds will rise, making them more prone to trapping outgoing energy; both processes have a warming effect. In contrast, clouds in high latitudes will be increasingly made of water droplets rather than ice crystals. This shift from fewer, larger ice crystals to smaller but more numerous water droplets will result in more of the incoming solar energy being reflected back to space and produce a cooling effect. Better understanding of how clouds respond to warming has led to more confidence than before that future changes in clouds will, overall, cause additional warming (i.e., by weakening the current cooling effect of clouds). This is called a *positive net cloud feedback.*

ACCEPTED VERSION SUBJECT TO FINAL EDITING

In summary, clouds will amplify rather than suppress the warming of the climate system in the future, as more greenhouse gases and fewer aerosols are released to the atmosphere by human activities.

[START FAQ7.2, FIGURE 1 HERE]

FAQ7.2, Figure 1: Interactions between clouds and the climate today and in a warmer future. Global warming is expected to alter the altitude (left) and the amount (centre) of clouds, which will amplify warming. On the other hand, cloud composition will change (right), offsetting some of the warming. Overall clouds are expected to amplify future warming.

FAQ 7.3: What is equilibrium climate sensitivity and how does it relate to future warming?

For a given future scenario, climate models project a range of changes in global surface temperature. This range is closely related to equilibrium climate sensitivity, or ECS, which measures how climate models respond to a doubling of carbon dioxide in the atmosphere. Models with high climate sensitivity project stronger future warming. Some climate models of the new generation are more sensitive than the range assessed in the IPCC Sixth Assessment Report. This leads to end-of-century global warming in some simulations of up to 2°C–3°C above the current IPCC best estimate. Although these higher warming levels are not expected to occur, high-ECS models are useful for exploring high impact, low-likelihood futures.

The *equilibrium climate sensitivity* (ECS) is defined as the long-term global warming caused by a doubling of carbon dioxide above its pre-industrial concentration. For a given emission scenario, much of the uncertainty in projections of future warming can be explained by the uncertainty in ECS (FAQ 7.3, Figure 1). The significance of equilibrium climate sensitivity has long been recognised, and the first estimate was presented by Swedish scientist Svante Arrhenius in 1896.

This Sixth Assessment Report concludes that there is a 90% or more chance (*very likely*) that the ECS is between 2°C and 5°C. This represents a significant reduction in uncertainty compared to the Fifth Assessment Report, which gave a 66% chance (*likely*) of ECS being between 1.5°C and 4.5°C. This reduction in uncertainty has been possible not through a single breakthrough or discovery but instead by combining evidence from many different sources and by better understanding their strengths and weaknesses.

There are four main lines of evidence for ECS. First, the self-reinforcing processes, called *feedback loops,* that amplify or dampen the warming in response to increasing carbon dioxide are now better understood. For example, warming in the Arctic melts sea ice, resulting in more open ocean area, which is darker and therefore absorbs more sunlight, further intensifying the initial warming. It remains challenging to represent realistically all the processes involved in these feedback loops, particularly those related to clouds (see FAQ 7.2). Such identified model errors are now taken into account, and other known, but generally weak, feedback loops that are usually not included in models are now included in the assessment of ECS.

Second, historical warming since early industrialisation provides strong evidence that climate sensitivity is not small. Since 1850, the concentration of carbon dioxide and other greenhouse gases have increased, and as a result the Earth has warmed by about 1.1ºC. However, relying on this industrial-era warming to estimate ECS is challenging, partly because some of the warming from greenhouse gases was offset by cooling from aerosol particles and partly because the ocean are still responding to past increases in carbon dioxide.

Third, evidence from ancient climates that had reached equilibrium with greenhouse gas concentrations, such as the coldest period of the last ice age around 20,000 years ago, or warmer periods further back in time, provide useful data on the ECS of the climate system (see FAQ 1.3). Fourth, statistical approaches linking model ECS values with observed changes, such as global warming since the 1970s, provide complementary evidence.

All four lines of evidence rely, to some extent, on climate models, and interpreting the evidence often benefits from model diversity and spread in modelled climate sensitivity. Furthermore, high-sensitivity models can provide important insights into futures that have a low likelihood of occurring but that could result in large impacts. But, unlike in previous assessments, climate models are not considered a line of evidence in their own right in the IPCC Sixth Assessment Report.

The ECS of the latest climate models is, on average, higher than that of the previous generation of models and also higher than this report's best estimate of 3.0°C. Furthermore, the ECS values in some of the new models are both above and below the 2°C to 5°C *very likely* range, and although such models cannot be ruled out as implausible solely based on their ECS, some of them do display climate change that is inconsistent with the observed when tested with ancient climates. A slight mismatch with models is only natural because

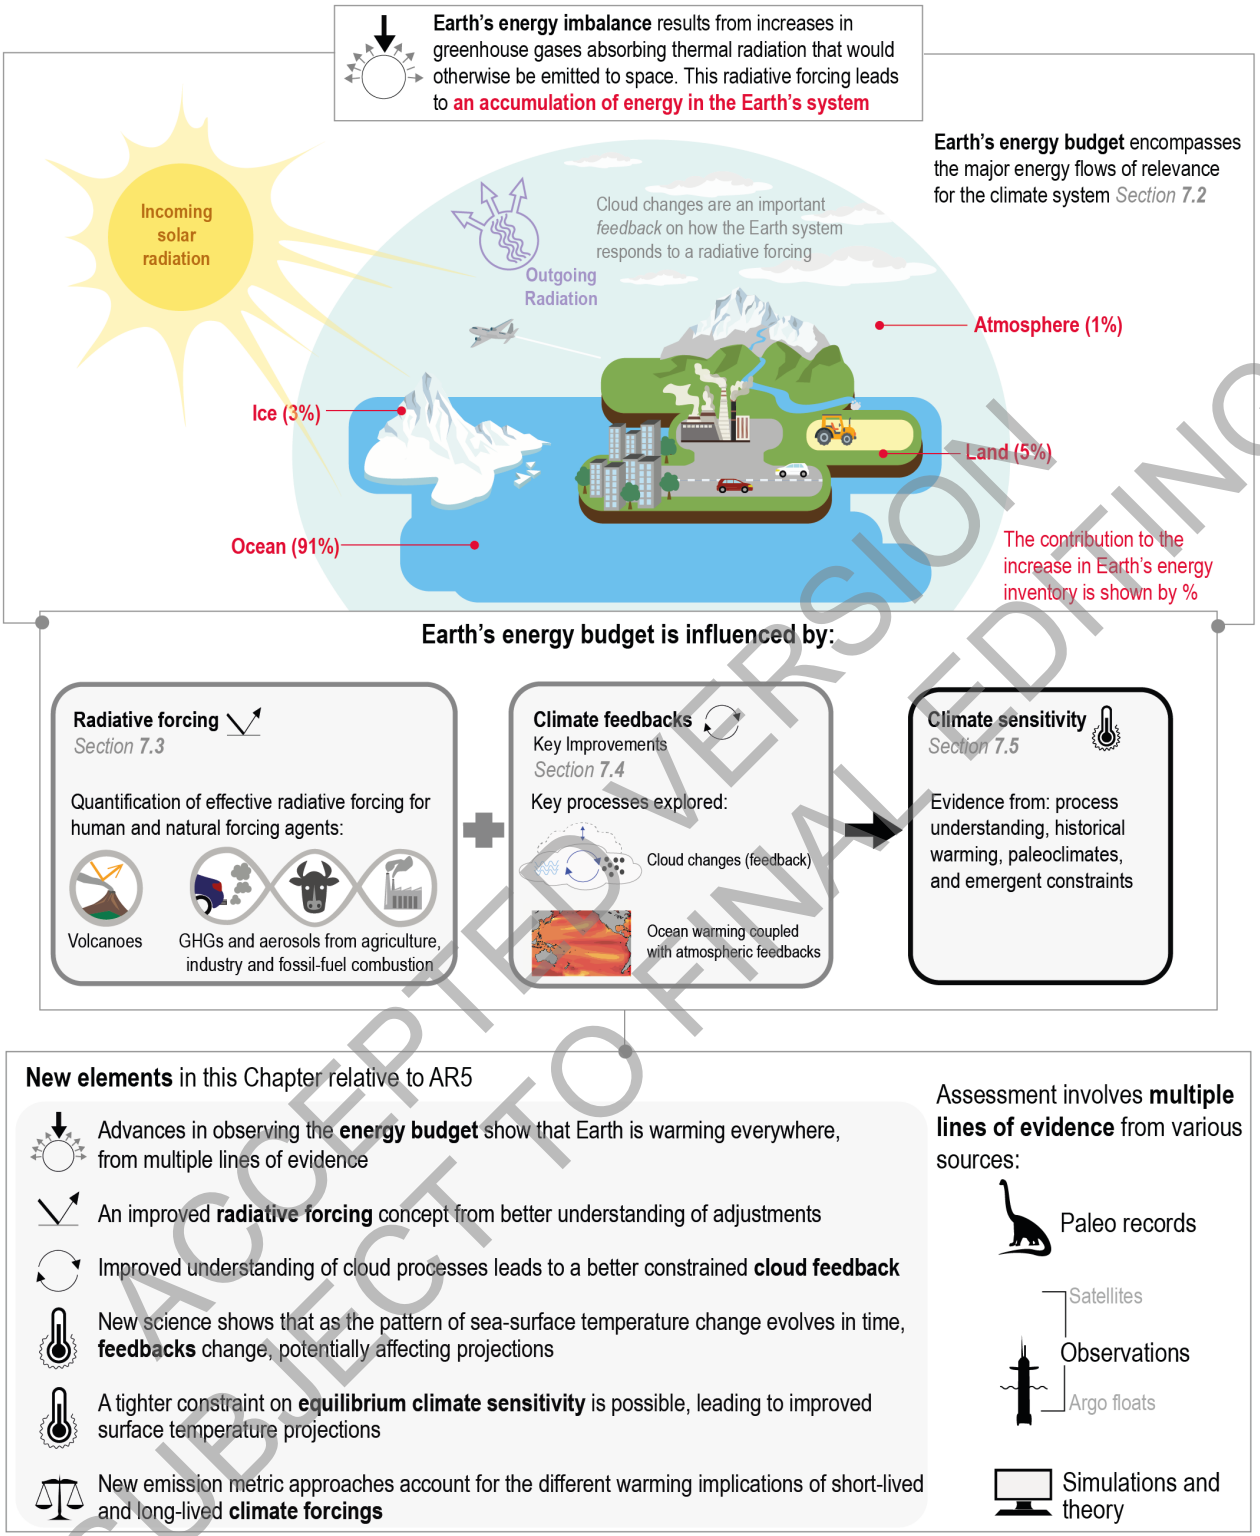
Figures



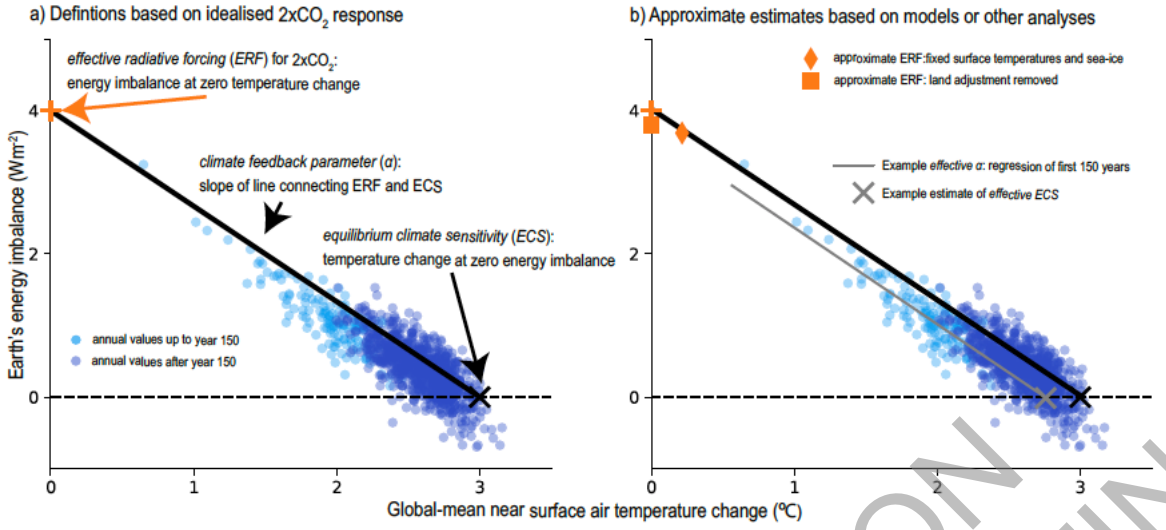


Figure 7.1: A visual abstract of the chapter, illustrating why the Earth's energy budget matters and how it relates to the underlying chapter assessment. The methods used to assess processes and key new findings relative to AR5 are highlighted.

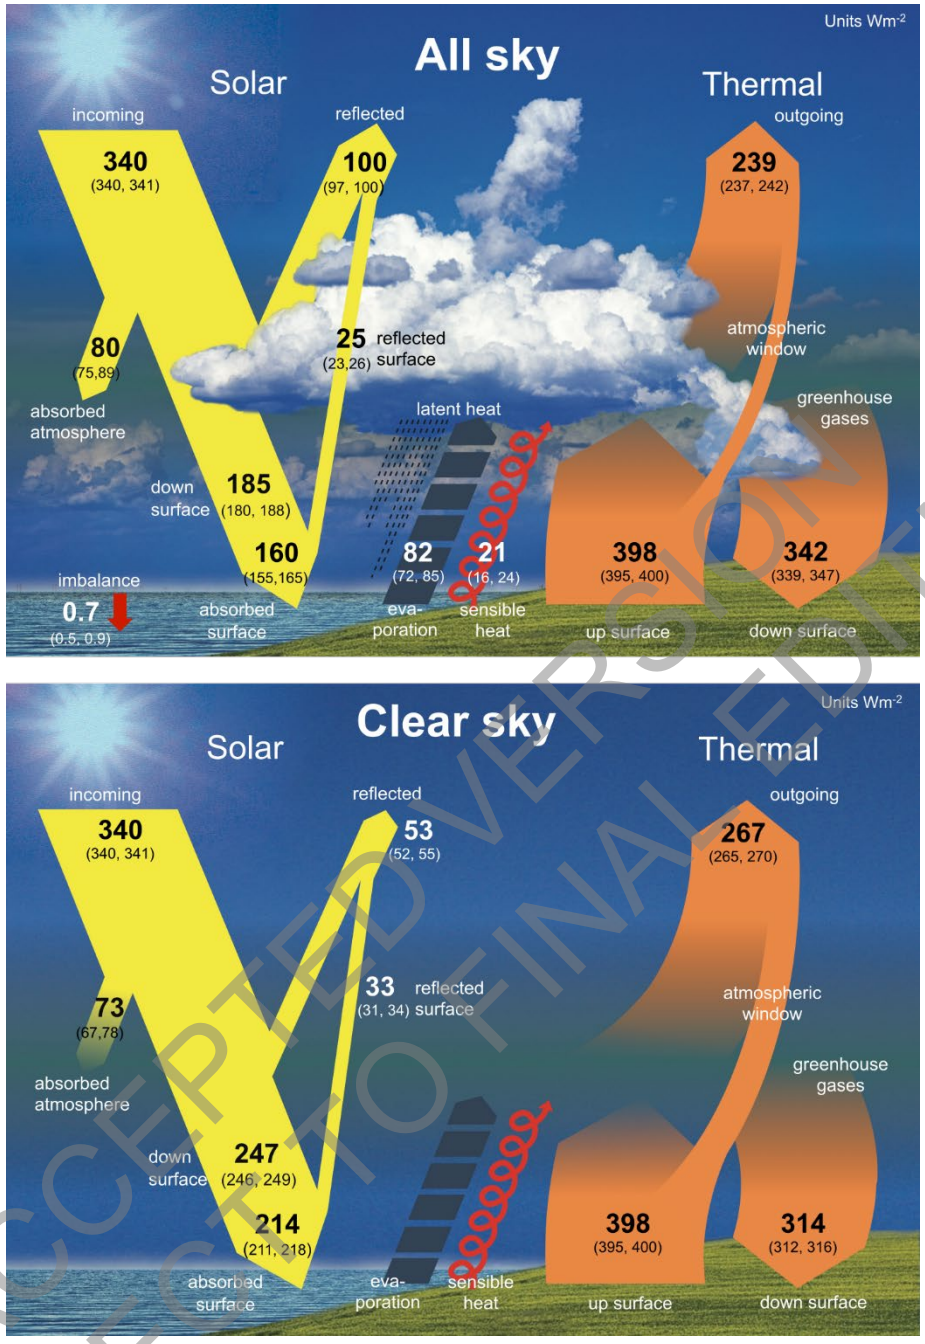
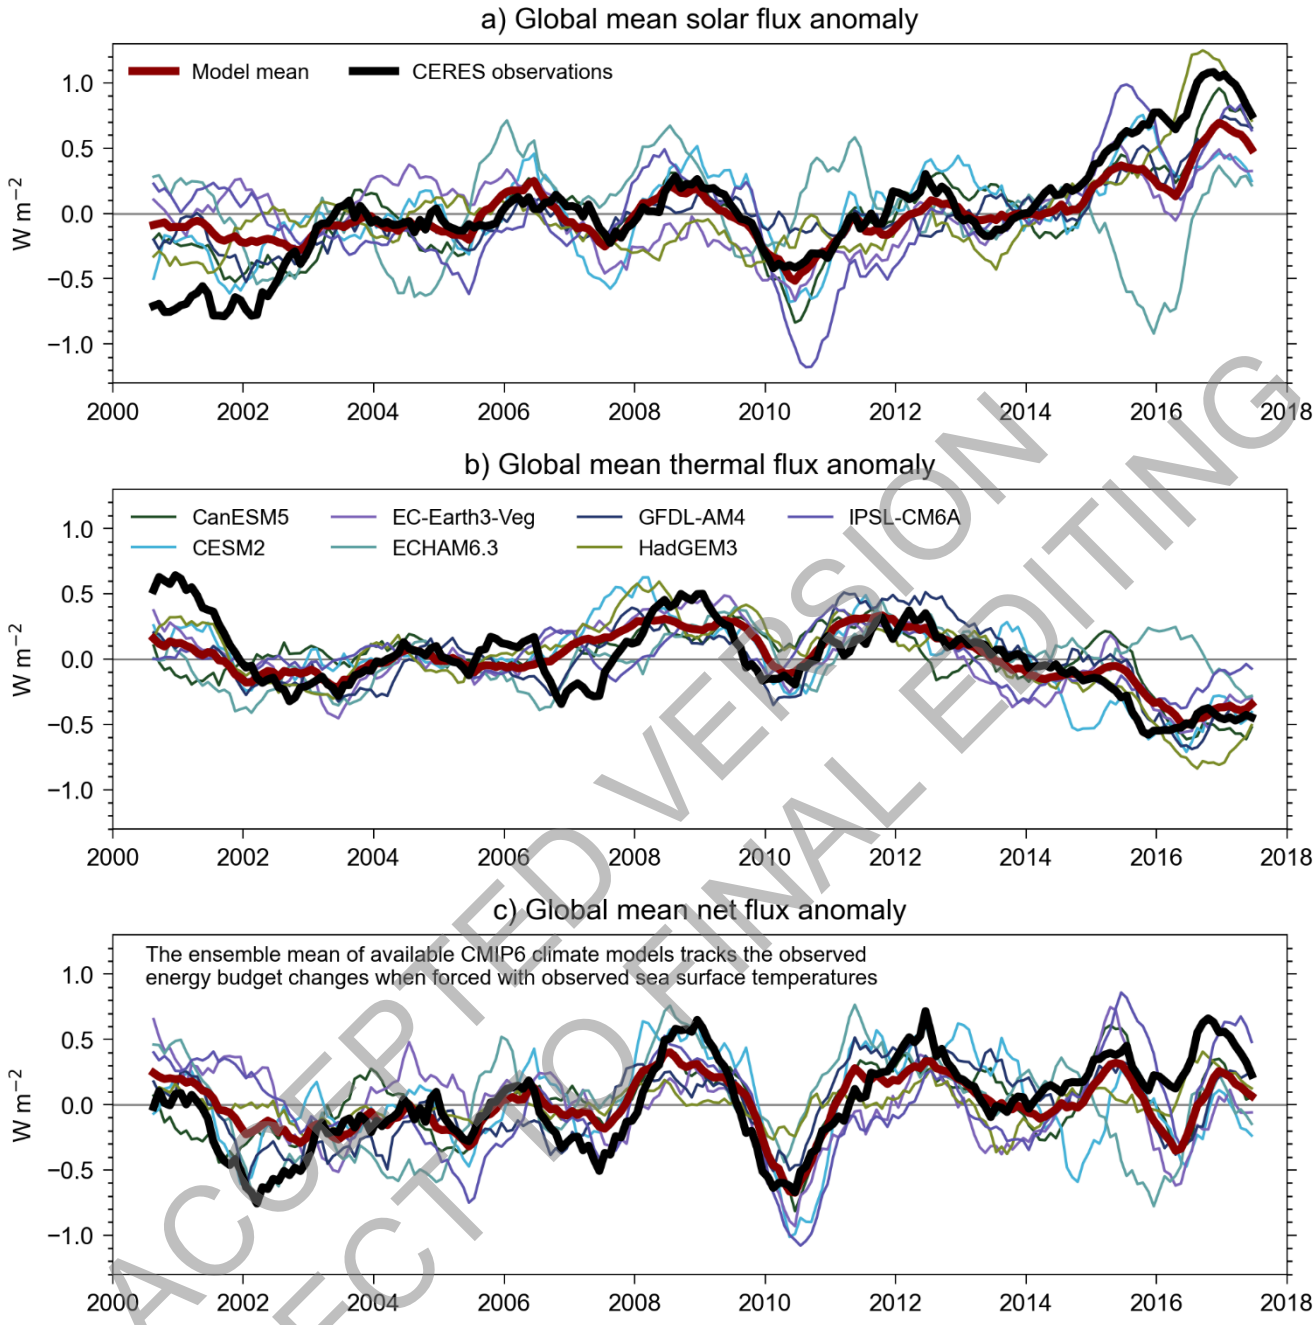
ACCEPTED VERSION SUBJECT TO FINAL EDITING

Box 7.1, Figure 1: Schematics of the forcing-feedback framework adopted within the assessment, following Equation 7.1. Illustrated is how the Earth's TOA net energy flux might evolve for a hypothetical doubling of atmospheric CO_2 concentration above preindustrial levels, where an initial positive energy imbalance (energy entering the Earth system, shown on the y-axis) is gradually restored towards equilibrium as the surface temperature warms (shown on the x-axis). a) illustrates the definitions of ERF for the special case of a doubling of atmospheric CO_2 concentration, the feedback parameter and the ECS. b) illustrates how approximate estimates of these metrics are made within the chapter and how these approximations might relate to the exact definitions adopted in panel a).

ACCEPTED VERSION SUBJECT TO FINAL EDITING





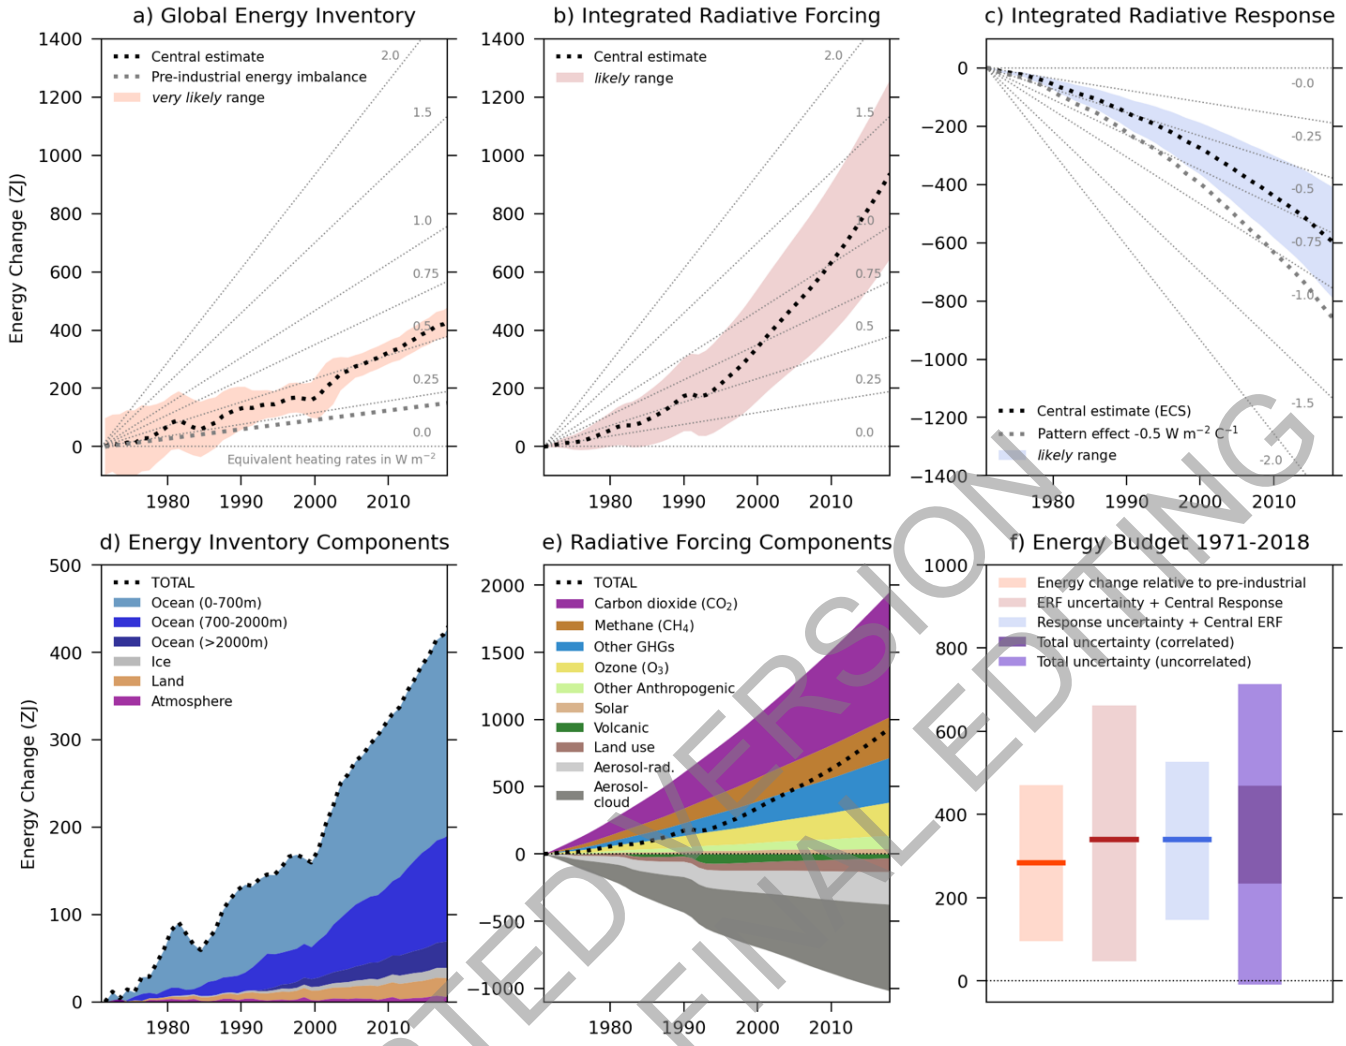


Figure 7.2: Schematic representation of the global mean energy budget of the Earth (upper panel), and its equivalent without considerations of cloud effects (lower panel). Numbers indicate best estimates for the magnitudes of the globally averaged energy balance components in W m^{-2} together with their uncertainty ranges in parentheses (5–95 % confidence range), representing climate conditions at the beginning of the 21st century. Note that the cloud-free energy budget shown in the lower panel is not the one that Earth would achieve in equilibrium when no clouds could form. It rather represents the global mean fluxes as determined solely by removing the clouds but otherwise retaining the entire atmospheric structure. This enables the quantification of the effects of clouds on the Earth energy budget and corresponds to the way clear-sky fluxes are calculated in climate models. Thus, the cloud-free energy budget is not closed and therefore the sensible and latent heat fluxes are not quantified in the lower panel. Adapted from Wild et al. (2015, 2019).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Figure 7.3: Anomalies in global mean all-sky TOA fluxes from EBAF Ed4.0 (solid black lines) and various CMIP6 climate models (coloured lines) in terms of (a) reflected solar, (b) emitted thermal and (c) net TOA fluxes. The multi-model means are additionally depicted as dotted black lines. Model fluxes stem from simulations driven with prescribed SSTs and all known anthropogenic and natural forcings. Shown are anomalies of 12-month running means. All flux anomalies are defined as positive downwards, consistent with the sign convention used throughout this chapter. The correlations between the multi-model means (dotted black lines) and the CERES records (solid black lines) for 12-month running means are 0.85, 0.73 and 0.81 for the global mean reflected solar, outgoing thermal and net TOA radiation, respectively. Adapted from Loeb et al. (2020). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

Box 7.2, Figure 1: Estimates of the net cumulative energy change (ZJ = 10^{21} Joules) for the period 1971–2018 associated with: (a) observations of changes in the Global Energy Inventory (b) Integrated Radiative Forcing; (c) Integrated Radiative Response. Black dotted lines indicate the central estimate with *likely* and *very likely* ranges as indicated in the legend. The grey dotted lines indicate the energy change associated with an estimated pre-industrial Earth energy imbalance of 0.2 W m^{-2} (panel a) and an illustration of an assumed pattern effect of –0.5 W m^{-2} $°C^{-1}$ (panel c). Background grey lines indicate equivalent heating rates in W m^{-2} per unit area of Earth's surface. Panels (d) and (e) show the breakdown of components, as indicated in the legend, for the Global Energy Inventory and Integrated Radiative Forcing, respectively. Panel (f) shows the Global Energy Budget assessed for the period 1971–2018, i.e. the consistency between the change in the Global Energy Inventory relative to pre-industrial and the implied energy change from Integrated Radiative Forcing plus Integrated Radiative Response under a number of different assumptions, as indicated in the figure legend, including assumptions of correlated and uncorrelated uncertainties in Forcing plus Response. Shading represents the *very likely* range for observed energy change relative to pre-industrial and *likely* range for all other quantities. Forcing and Response timeseries are expressed relative to a baseline period of 1850–1900. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

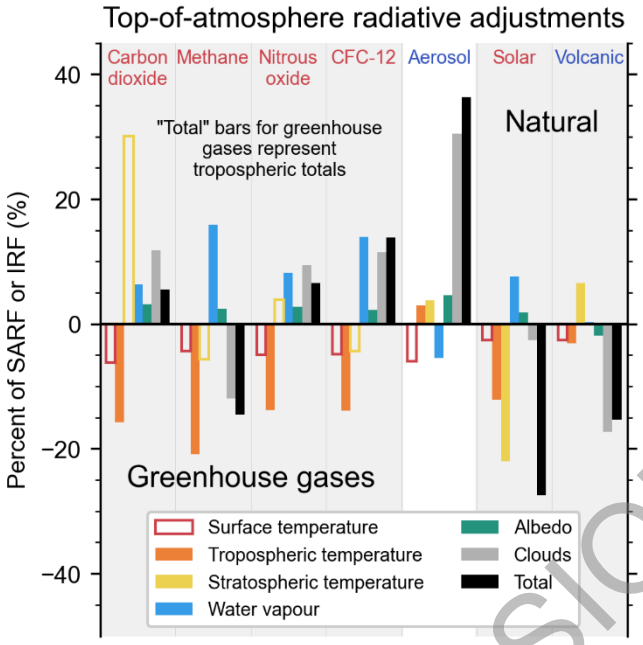

Figure 7.4: Radiative adjustments at top of atmosphere for seven different climate drivers as a proportion of forcing. Tropospheric temperature (orange), stratospheric temperature (yellow), water vapour (blue), surface albedo (green), clouds (grey) and the total adjustment (black) is shown. For the greenhouse gases (carbon dioxide, methane, nitrous oxide, CFC-12) the adjustments are expressed as a percentage of SARF, whereas for aerosol, solar and volcanic forcing they are expressed as a percentage of IRF. Land surface temperature response (outline red bar) is shown, but included in the definition of forcing. Data from Smith et al. (2018b) for carbon dioxide and methane, Smith et al. (2018b) and Gray et al. (2009) for solar, Hodnebrog et al. (2020b) for nitrous oxide and CFC-12, Smith et al. (2020a) for aerosol, and Marshall et al. (2020) for volcanic. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

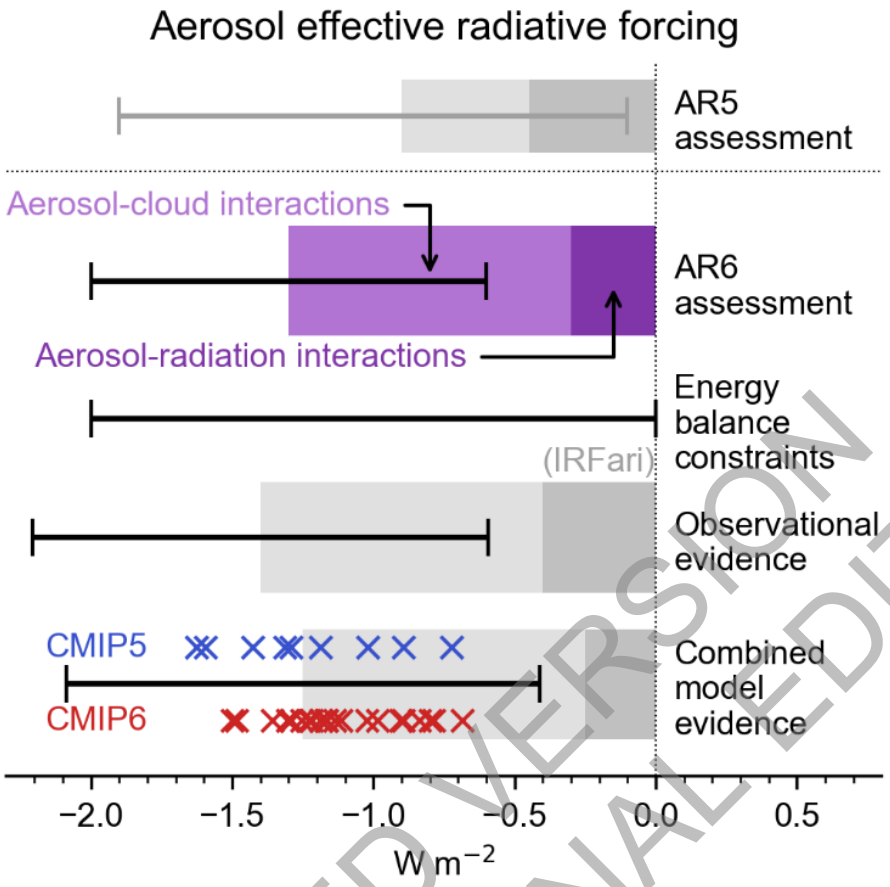

Figure 7.5: **Net aerosol effective radiative forcing from different lines of evidence.** The headline AR6 assessment of –1.3 [–2.0 to –0.6] W m^{-2} is highlighted in purple for 1750–2014 and compared to the AR5 assessment of –0.9 [–1.9 to –0.1] W m^{-2} for 1750–2011. The evidence comprising the AR6 assessment is shown below this: energy balance constraints [–2 to 0 W m^{-2} with no best estimate], observational evidence from satellite retrievals of –1.4 [–2.2 to –0.6] W m^{-2}, and climate model-based evidence of –1.25 [–2.1 to –0.4] W m^{-2}. Estimates from individual CMIP5 (Zelinka et al., 2014) and CMIP6 (Smith et al., 2020a and Table 7.6) models are depicted by blue and red crosses respectively. For each line of evidence the assessed best-estimate contributions from ERFari and ERFaci are shown with darker and paler shading respectively. The observational assessment for ERFari is taken from the IRFari. Uncertainty ranges are given in black bars for the total aerosol ERF and depict *very likely* ranges. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

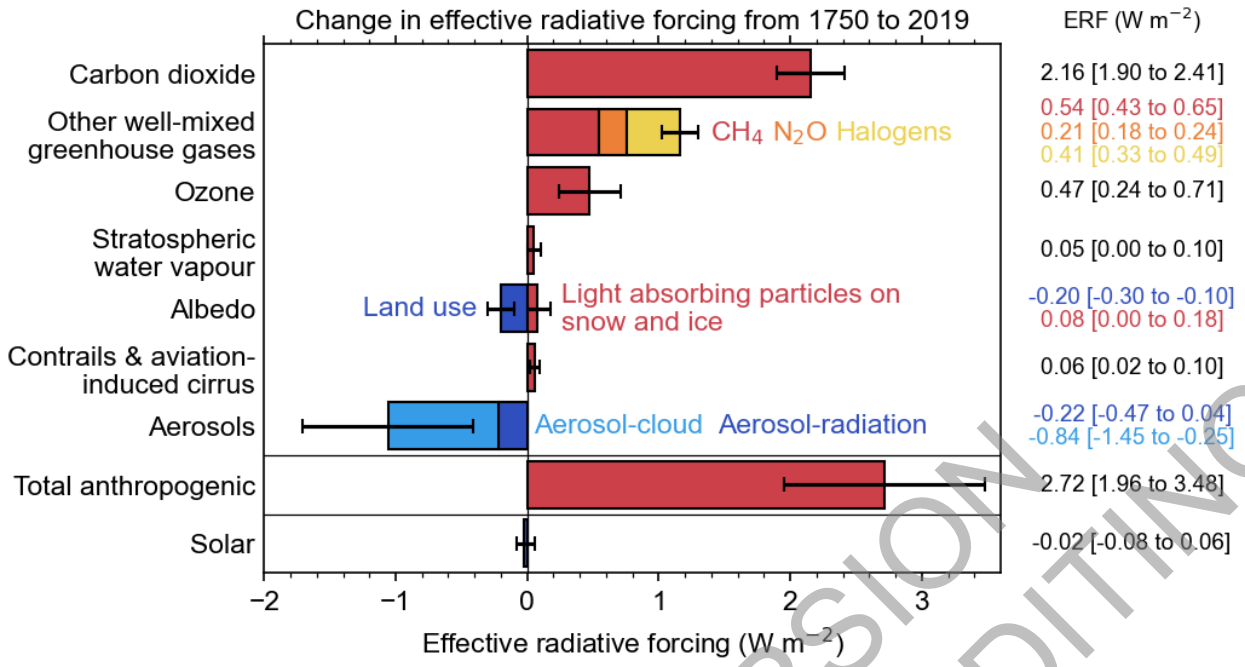

Figure 7.6: Change in effective radiative forcing from 1750 to 2019 by contributing forcing agents (carbon dioxide, other well-mixed greenhouse gases (WMGHGs), ozone, stratospheric water vapour, surface albedo, contrails and aviation-induced cirrus, aerosols, anthropogenic total, and solar). Solid bars represent best estimates, and *very likely* (5–95%) ranges are given by error bars. Non-CO_2 WMGHGs are further broken down into contributions from methane (CH_4), nitrous oxide (N_2O) and halogenated compounds. Surface albedo is broken down into land use changes and light absorbing particles on snow and ice. Aerosols are broken down into contributions from aerosol-cloud interactions (ERFaci) and aerosol-radiation interactions (ERFari). For aerosols and solar, the 2019 single-year values are given (Table 7.8) that differ from the headline assessments in both cases. Volcanic forcing is not shown due to the episodic nature of volcanic eruptions. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

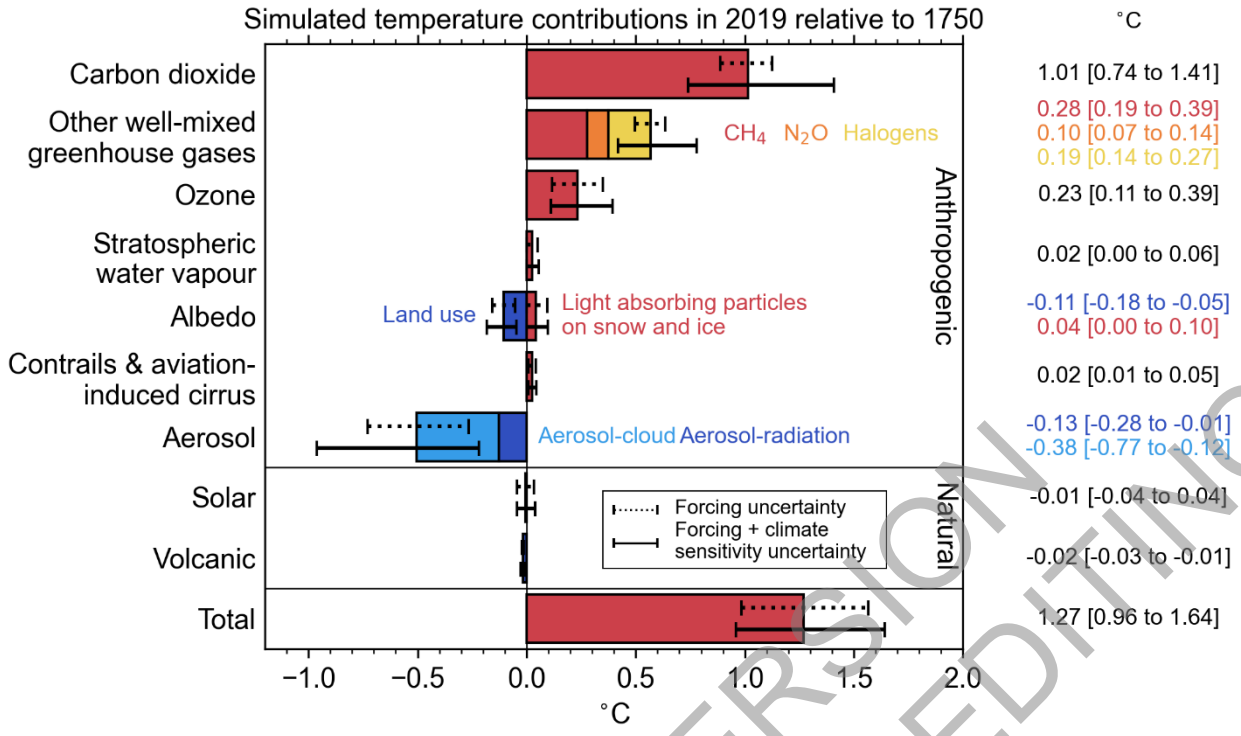

Figure 7.7: The contribution of forcing agents to 2019 temperature change relative to 1750 produced using the two-layer emulator (Supplementary Material 7.SM.2), constrained to assessed ranges for key climate metrics described in Cross-Chapter Box 7.1. The results are from a 2,237-member ensemble. Temperature contributions are expressed for carbon dioxide, other well-mixed greenhouse gases (WMGHGs), ozone, stratospheric water vapour, surface albedo, contrails and aviation-induced cirrus, aerosols, solar, volcanic, and total. Solid bars represent best estimates, and *very likely* (5–95%) ranges are given by error bars. Dashed error bars show the contribution of forcing uncertainty alone, using best estimates of ECS (3.0°C), TCR (1.8°C) and two-layer model parameters representing the CMIP6 multi-model mean. Solid error bars show the combined effects of forcing and climate response uncertainty using the distribution of ECS and TCR from Tables 7.13 and 7.14, and the distribution of calibrated model parameters from 44 CMIP6 models. Non-CO_2 WMGHGs are further broken down into contributions from methane (CH_4), nitrous oxide (N_2O) and halogenated compounds. Surface albedo is broken down into land use changes and light absorbing particles on snow and ice. Aerosols are broken down into contributions from aerosol-cloud interactions (ERFaci) and aerosol-radiation interactions (ERFari). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

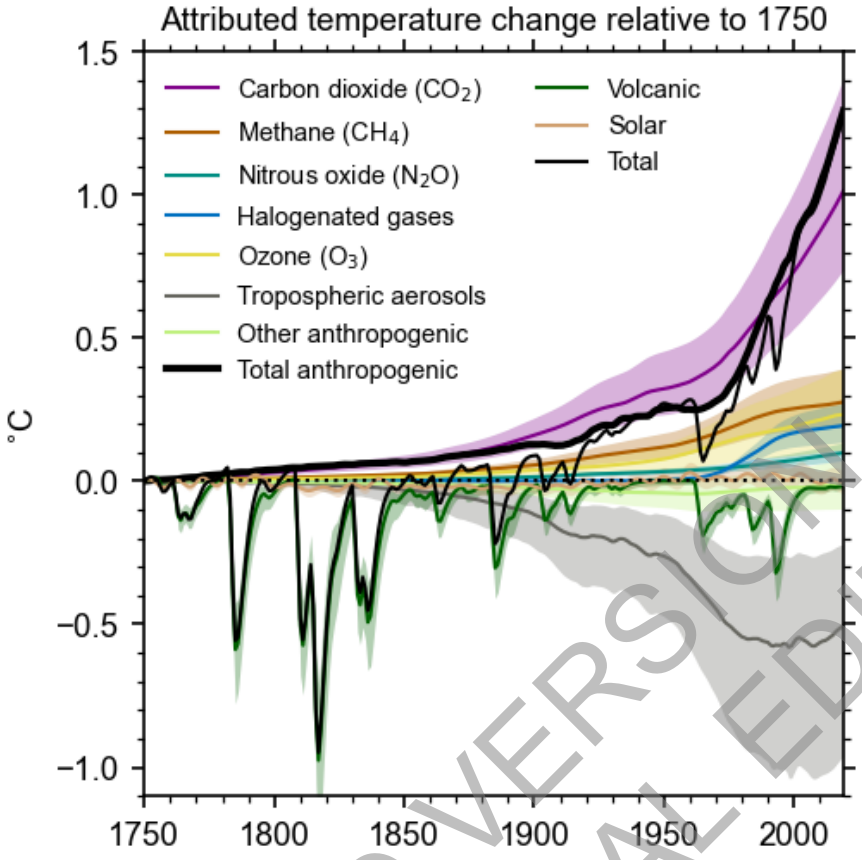
ACCEPTED VERSION SUBJECT TO FINAL EDITING



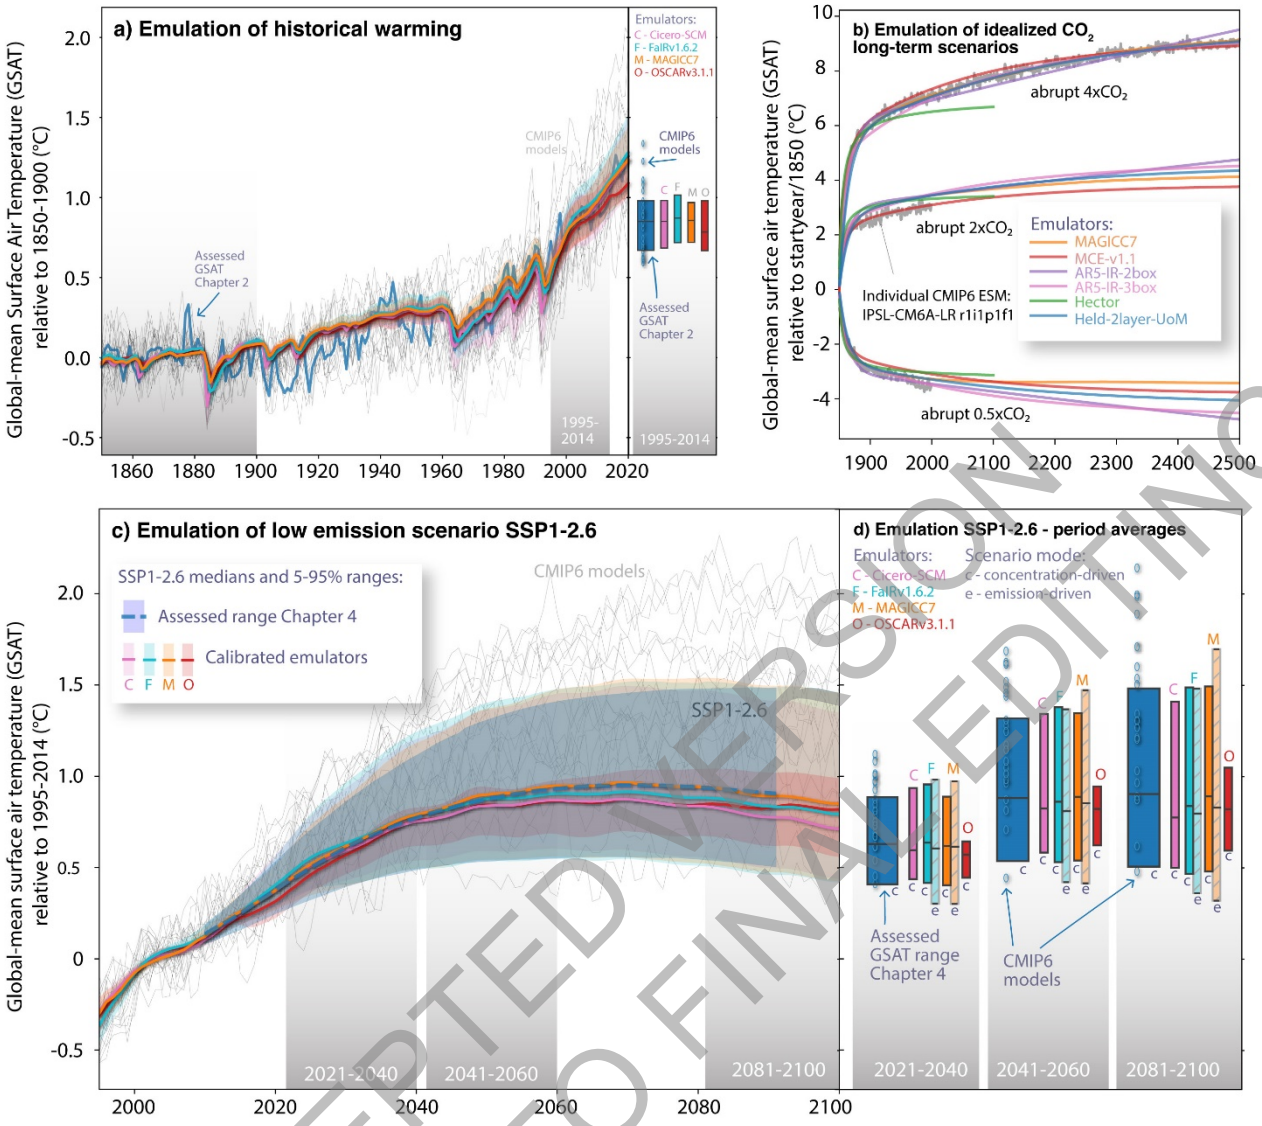


Figure 7.8: Attributed global near-surface air temperature change (GSAT) from 1750 to 2019 produced using the two-layer emulator (Supplementary Material 7.SM.2), forced with ERF derived in this chapter (displayed in Chapter 2, Figure 2.10) and climate response constrained to assessed ranges for key climate metrics described in Cross-Chapter Box 7.1. The results shown are the medians from a 2,237-member ensemble that encompasses uncertainty in forcing and climate response (year-2019 best estimates and uncertainties are shown in Figure 7.7 for several components). Temperature contributions are expressed for carbon dioxide, methane, nitrous oxide, other well-mixed greenhouse gases (WMGHGs), ozone, aerosols, other anthropogenic forcings, total anthropogenic, solar, volcanic, and total. Shaded uncertainty bands show *very likely* ranges. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Cross-Chapter Box 7.1, Figure 1: A comparison between the global-mean surface air temperature response of various calibrated simple climate models, assessed ranges and Earth System Models. The top panels compare the assessed historical GSAT time series (Chapter 2, Section 2.3.1) with four multi-gas emulators calibrated to replicate numerous assessed ranges (Cross-Chapter Box 7.1, Table 2 below) (panel a) and also compares idealized CO_2-only concentration scenario response for one ESM (IPSL CM6A-LR) and multiple emulators which participated in RCMIP Phase 1 (Nicholls et al., 2020) calibrated to that single ESM (panel b). The bottom panels compare this report's assessed ranges for GSAT warming (Chapter 4, Box 4.1) under the multi-gas scenario SSP1-2.6 with the same calibrated emulators as in panel a (panel c and d). For context, a range of CMIP6 ESM results are also shown (thin lines in bottom-left panel c and open circles in bottom-right panel d). Panel b) adapted from Nicholls et al. (2020). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

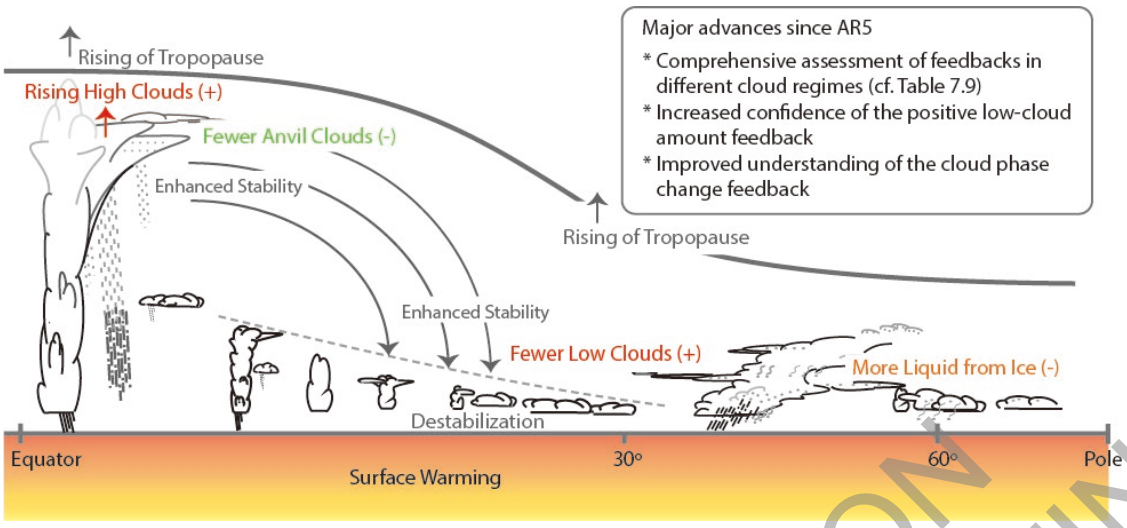

Figure 7.9: Schematic cross section of diverse cloud responses to surface warming from the tropics to polar regions. Thick solid and dashed curves indicate the tropopause and the subtropical inversion layer in the current climate, respectively. Thin grey text and arrows represent robust responses in the thermodynamic structure to greenhouse warming, of relevance to cloud changes. Text and arrows in red, orange and green show the major cloud responses assessed with *high*, *medium* and *low confidence*, respectively, and the sign of their feedbacks to the surface warming is indicated in the parenthesis. Major advances since AR5 are listed in a box.

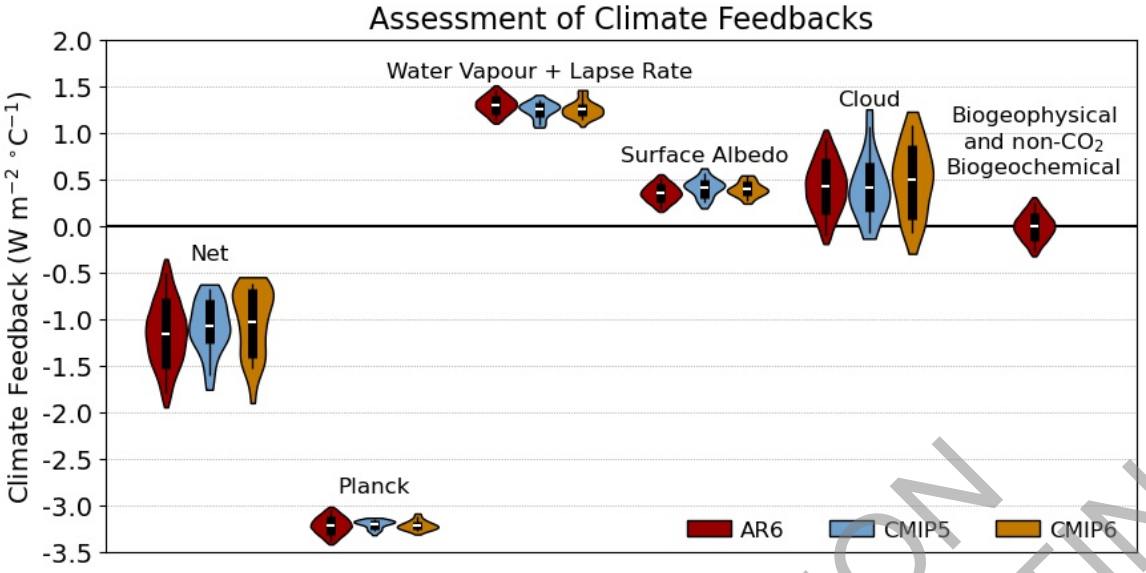

Figure 7.10: Global-mean climate feedbacks estimated in *abrupt4xCO2* simulations of 29 CMIP5 models (light blue) and 49 CMIP6 models (orange), compared with those assessed in this Report (red). Individual feedbacks for CMIP models are averaged across six radiative kernels as computed in Zelinka et al. (2020). The white line, black box and vertical line indicate the mean, 66% and 90% ranges, respectively. The shading represents the probability distribution across the full range of GCM/ESM values and for the 2.5–97.5 percentile range of the AR6 normal distribution. The unit is W m^{-2} °C^{-1}. Feedbacks associated with biogeophysical and non-CO_2 biogeochemical processes are assessed in AR6, but they are not explicitly estimated from GCMs/ESMs in CMIP5 and CMIP6. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

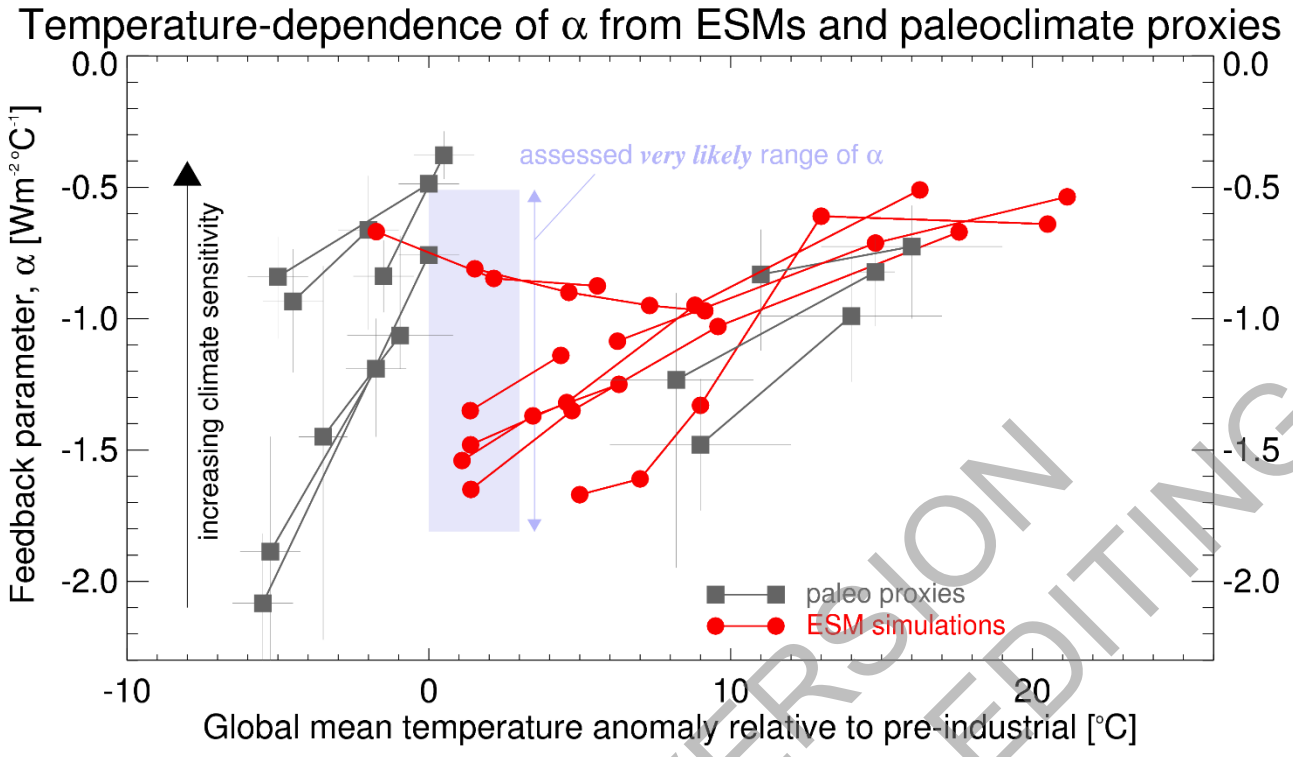

Figure 7.11: Feedback parameter, α (W m^{-2} °C^{-1}), as a function of global mean surface air temperature anomaly relative to preindustrial, for ESM simulations (red circles and lines) (Caballero and Huber, 2013; Jonko et al., 2013; Meraner et al., 2013; Good et al., 2015; Duan et al., 2019; Mauritsen et al., 2019; Stolpe et al., 2019; Zhu et al., 2019), **and derived from paleoclimate proxies (grey squares and lines)** (von der Heydt et al., 2014; Anagnostou et al., 2016, 2020; Friedrich et al., 2016; Royer, 2016; Shaffer et al., 2016; Köhler et al., 2017; Snyder, 2019; Stap et al., 2019). For the ESM simulations, the value on the *x*-axis refers to the average of the temperature before and after the system has equilibrated to a forcing (in most cases a CO_2 doubling), and is expressed as an anomaly relative to an associated pre-industrial global mean temperature from that model. The light blue shaded square extends across the assessed range of α (Table 7.10) on the *y*-axis, and on the *x*-axis extends across the approximate temperature range over which the assessment of α is based (taken as from zero to the assessed central value of ECS (Table 7.13). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

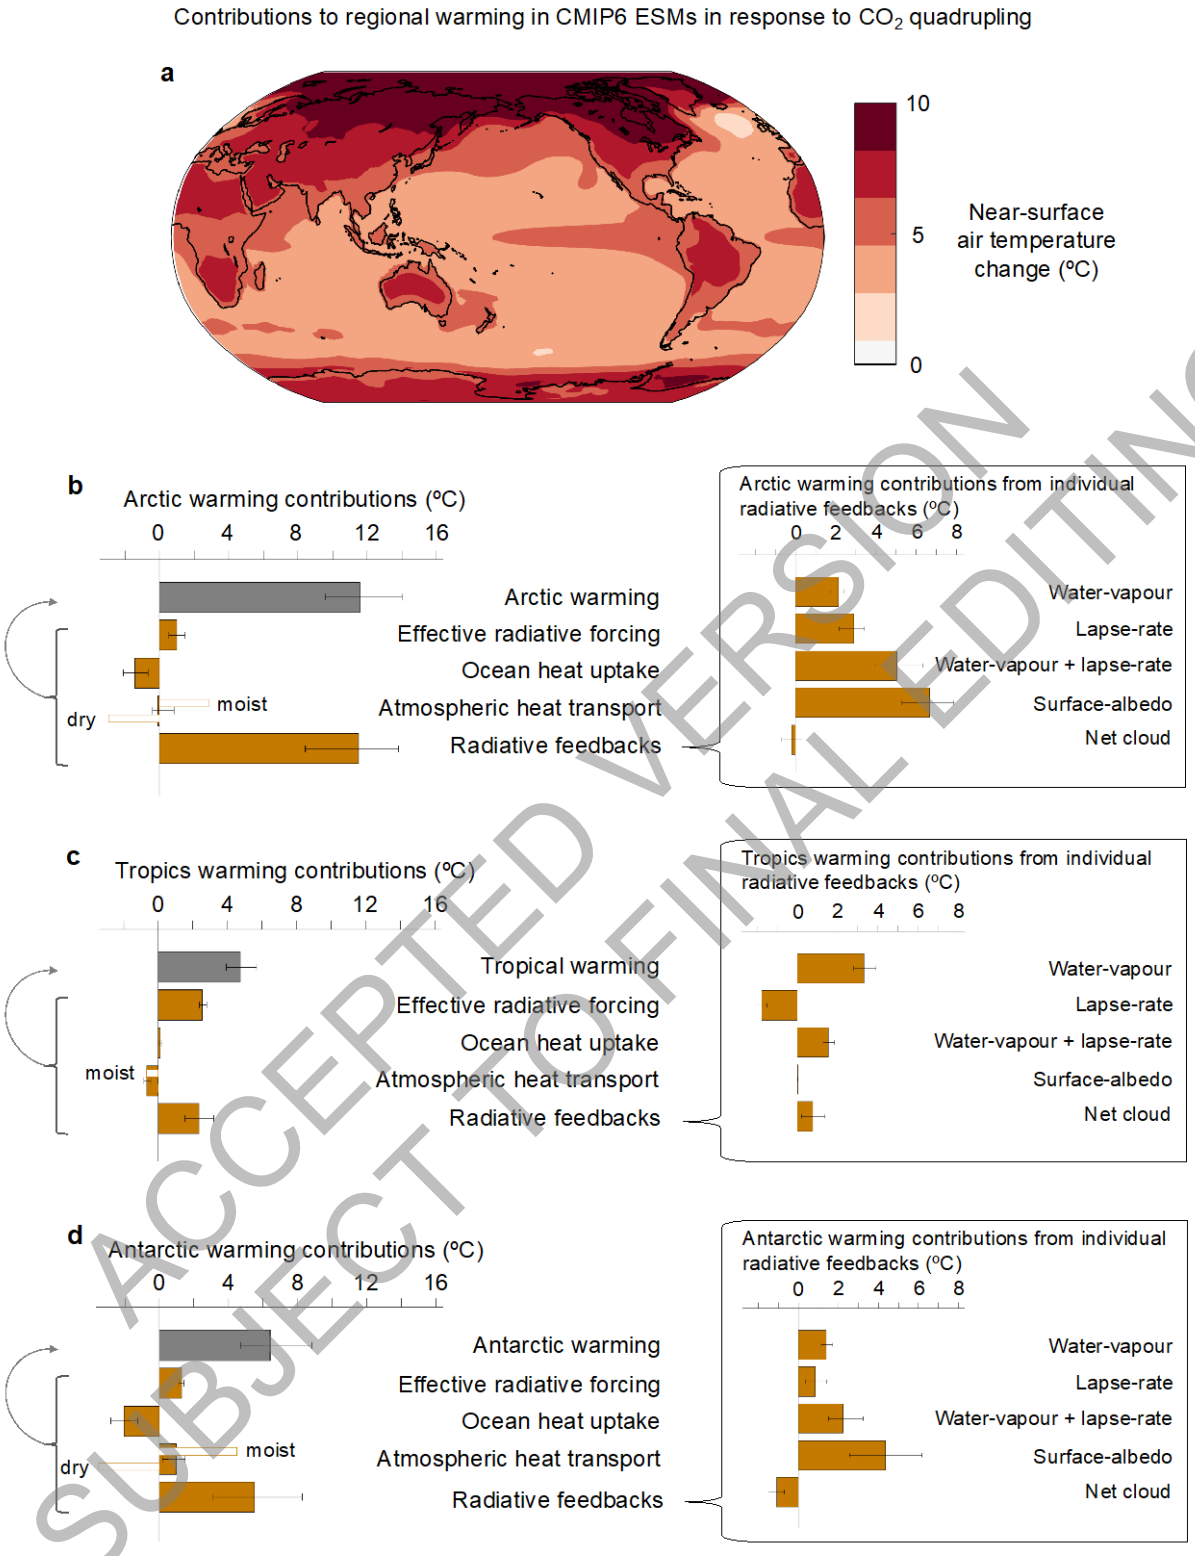
ACCEPTED VERSION SUBJECT TO FINAL EDITING



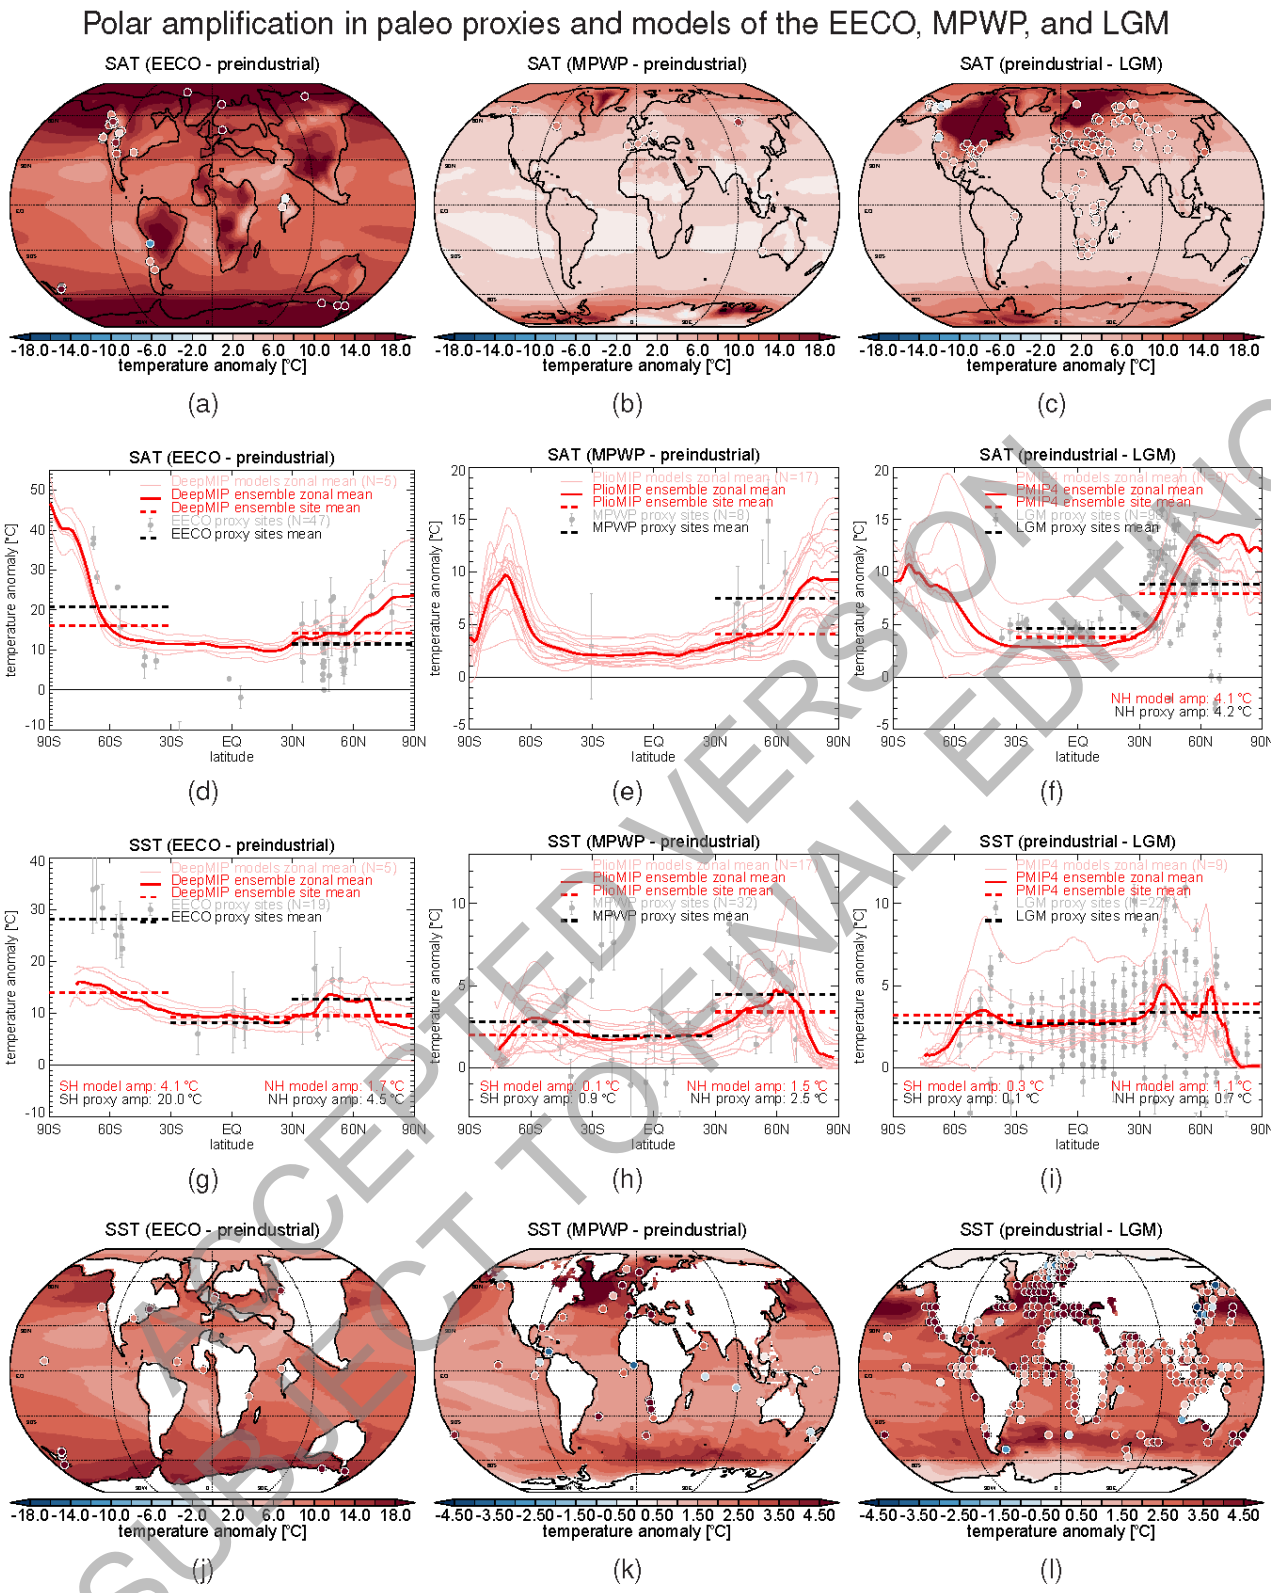


Figure 7.12: Contributions of effective radiative forcing, ocean heat uptake, atmospheric heat transport, and radiative feedbacks to regional surface temperature changes at year 100 of *abrupt4xCO2* simulations of CMIP6 ESMs. (a) Pattern of near-surface air temperature change. (b-d) Contributions to net Arctic (>60°N), tropical (30°S – 30°N), and Antarctic (<60°S) warming calculated by dividing regional-average energy inputs by the magnitude of the regional-average Planck response. The contributions from radiative forcing, changes in moist, dry-static, and total atmospheric energy transport, ocean heat uptake, and radiative feedbacks (orange bars) all sum to the value of net warming (grey bar).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Inset shows regional warming contributions associated with individual feedbacks, all summing to the total feedback contribution. Uncertainties show the interquartile range (25th and 75th percentiles) across models. The warming contributions (units of °C) for each process are diagnosed by calculating the energy flux (units of W m^{-2}) that each process contributes to the atmosphere over a given region, either at the TOA or surface, then dividing that energy flux by the magnitude of the regional Planck response (around 3.2 W m^{-2} $°C^{-1}$ but varying with region). By construction, the individual warming contributions sum to the total warming in each region. Radiative kernel methods (see Section 7.4.1) are used to decompose the net energy input from radiative feedbacks into contributions from changes in atmospheric water vapour, lapse-rate, clouds, and surface albedo (Zelinka et al. (2020) using the Huang et al. (2017) radiative kernel). The CMIP6 models included are those analysed by Zelinka et al. (2020) and the warming contribution analysis is based on that of Goosse et al. (2018). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

Figure 7.13: Polar amplification in paleo proxies and models of the early Eocene climatic optimum (EECO), the mid-Pliocene warm period (MPWP), and the Last Glacial Maximum (LGM). Temperature anomalies compared with pre-industrial (equivalent to CMIP6 simulation *piControl*) are shown for the high-CO_2 EECO and MPWP time periods, and for the low-CO_2 LGM (expressed as pre-industrial minus LGM). (a,b,c) Modelled near-surface air temperature anomalies for ensemble-mean simulations of the (a) EECO (Lunt et al., 2021), (b) MPWP (Haywood et al., 2020; Zhang et al., 2021), and (c) LGM (Kageyama et al., 2021; Zhu et al., 2021). Also shown are proxy near-surface air temperature anomalies (coloured circles). (d,e,f) Proxy near-surface air temperature anomalies (grey circles), including published

uncertainties (grey vertical bars), model ensemble mean zonal mean anomaly (solid red line) for the same model ensembles as in (a,b,c), light red lines show the modelled temperature anomaly for the individual models that make up each ensemble (LGM, N=9; MPWP, N=17; EECO, N=5). Black dashed lines show the average of the proxy values in each latitude bands 90°S to 30°S, 30°S to 30°N, and 30°N to 90°N. Red dashed lines show the same banded average in the model ensemble mean, calculated from the same locations as the proxies. Black and red dashed lines are only shown if there are 5 or more proxy points in that band. Mean differences between the 90°S/N to 30°S/N and 30°S to 30°N bands are quantified for the models and proxies in each plot. Panels (g,h,i) are like panels (d,e,f) but for SST instead of near-surface air temperature. Panels (j,k,l) are like panels (a,b,c) but for SST instead of near-surface air temperature. For the EECO maps (a,j), the anomalies are relative to the zonal mean of the pre-industrial, due to the different continental configuration. Proxy datasets are (a,d) Hollis et al. (2019), (b,e) Salzmann et al. (2013); Vieira et al. (2018), (c,f) Cleator et al. (2020) at the sites defined in Bartlein et al. (2011), (g,j)) Hollis et al. (2019), (h,k) McClymont et al. (2020) (i,l) Tierney et al. (2020b). Where there are multiple proxy estimations at a single site, a mean is taken. Model ensembles are (a,d,g,j) DeepMIP (only model simulations carried out with a mantle-frame paleogeography, and carried out under CO_2 concentrations within the range assessed in Chapter 2, Table 2.2, are shown), (b,e,h,k) PlioMIP, and (c,f,i,l) PMIP4. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

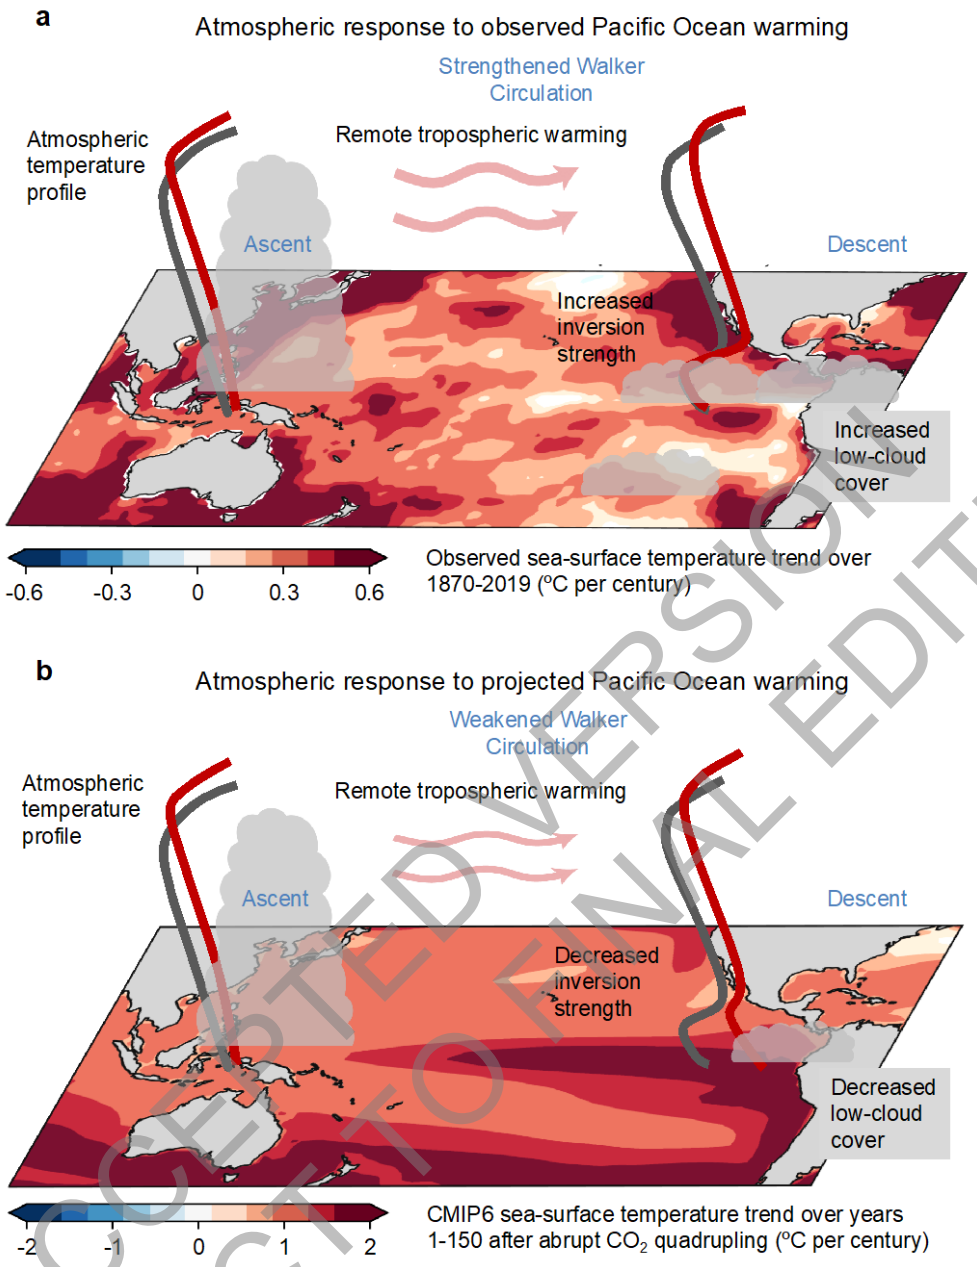

Figure 7.14: Illustration of tropospheric temperature and low-cloud response to observed and projected Pacific Ocean sea-surface temperature trends; adapted from Mauritsen (2016). (a) Atmospheric response to linear sea-surface temperature trend observed over 1870–2019 (HadISST1 dataset; Rayner et al., 2003). (b) Atmospheric response to linear sea-surface temperature trend over 150 years following *abrupt4xCO2* forcing as projected by CMIP6 ESMs (Dong et al., 2020). Relatively large historical warming in the western tropical Pacific has been communicated aloft (a shift from grey to red atmospheric temperature profile), remotely warming the tropical free troposphere and increasing the strength of the inversion in regions of the tropics where warming has been slower, such as the eastern equatorial Pacific. In turn, an increased inversion strength has increased the low-cloud cover (Zhou et al., 2016) causing an anomalously-negative cloud and lapse-rate feedbacks over the historical record (Andrews et al., 2018; Marvel et al., 2018). Relatively large projected warming in the eastern tropical Pacific is trapped near the surface (shift from grey to red atmospheric temperature profile), decreasing the strength of the inversion locally. In turn, a decreased inversion strength combined with surface warming is projected to decrease the low-cloud cover, causing the cloud and lapse-rate feedbacks to become less negative in the future. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

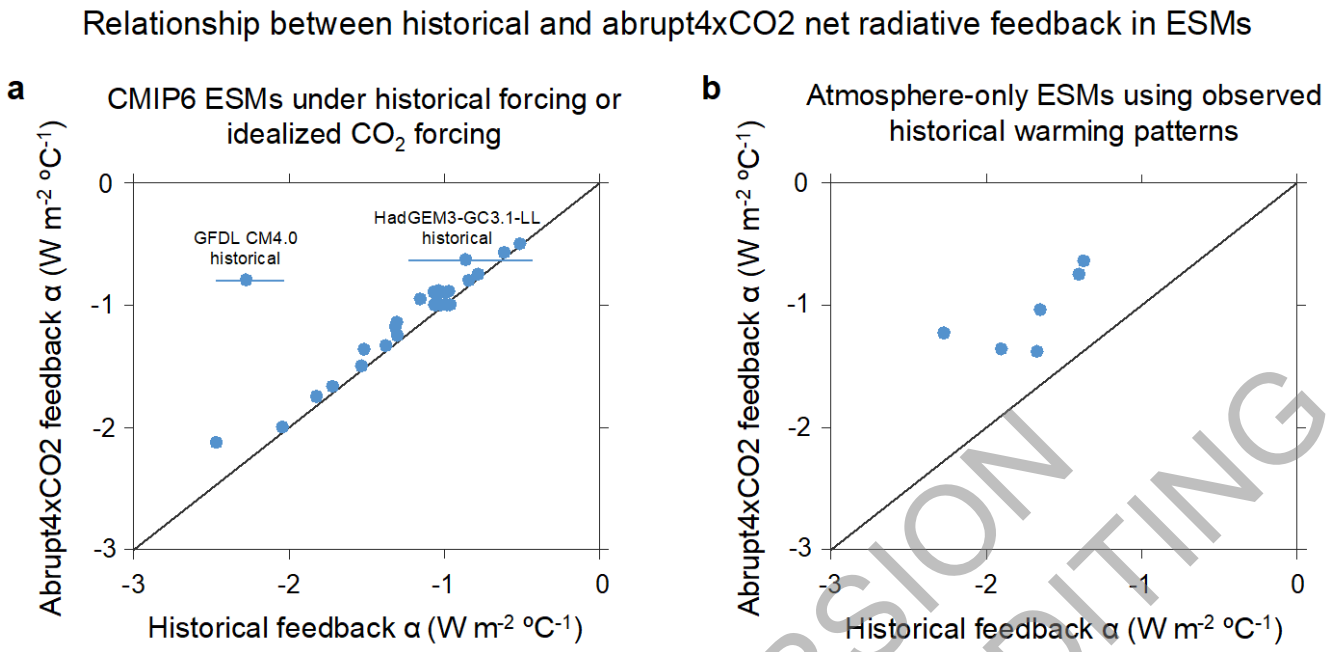

Figure 7.15: Relationship between *historical* and *abrupt4xCO2* net radiative feedbacks in ESMs. (a) Radiative feedbacks in CMIP6 ESMs estimated under historical forcing (values for GFDL CM4.0 and HadGEM3-CG3.1-LL from Winton et al. (2020) and Andrews et al. (2019), respectively); horizontal lines show the range across ensemble members. The other points show effective feedback values for 29 ESMs estimated using regression over the first 50 years of *abrupt4xCO2* simulations as an analogue for historical warming (Dong et al., 2020). (b) Historical radiative feedbacks estimated from atmosphere-only ESMs with prescribed observed sea-surface temperature and sea-ice concentration changes (Andrews et al. 2018) based on a linear regression of global TOA radiation against global near-surface air temperature over the period 1870–2010 (pattern of warming similar to Figure 7.14a) and compared with equilibrium feedbacks in a *abrupt4xCO2* simulations of coupled versions of the same ESMs (pattern of warming similar to Figure 7.14b). In all cases, the equilibrium feedback magnitudes are estimated as CO_2 ERF divided by ECS where ECS is derived from regression over years 1–150 of *abrupt4xCO2* simulations (Box 7.1); similar results are found if the equilibrium feedback is estimated directly from the slope of the linear regression. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

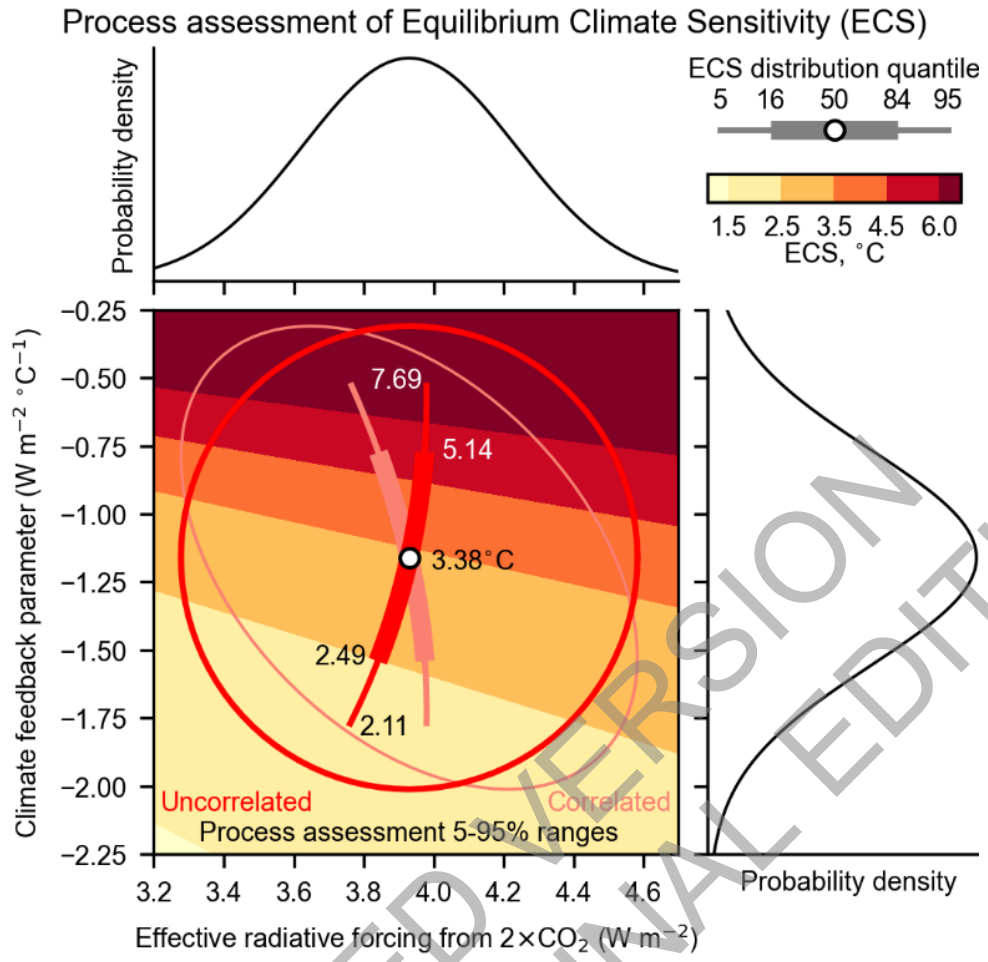

Figure 7.16: Probability distributions of ERF to CO_2 doubling ($\Delta F_{2\times CO2}$, top) and the net climate feedback (α, right), derived from process-based assessments in Sections 7.3.2 and 7.4.2. Middle panel shows the joint probability density function calculated on a two-dimensional plane of $\Delta F_{2\times CO2}$ and α (red), on which the 90% range shown by an ellipse is imposed to the background theoretical values of ECS (colour shading). The white dot, thick and thin curves in the ellipse represent the mean, *likely* and *very likely* ranges of ECS. An alternative estimation of the ECS range (pink) is calculated by assuming that $\Delta F_{2\times CO2}$ and α have a covariance. The assumption about the co-dependence between $\Delta F_{2\times CO2}$ and α does not alter the mean estimate of ECS but affects its uncertainty. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

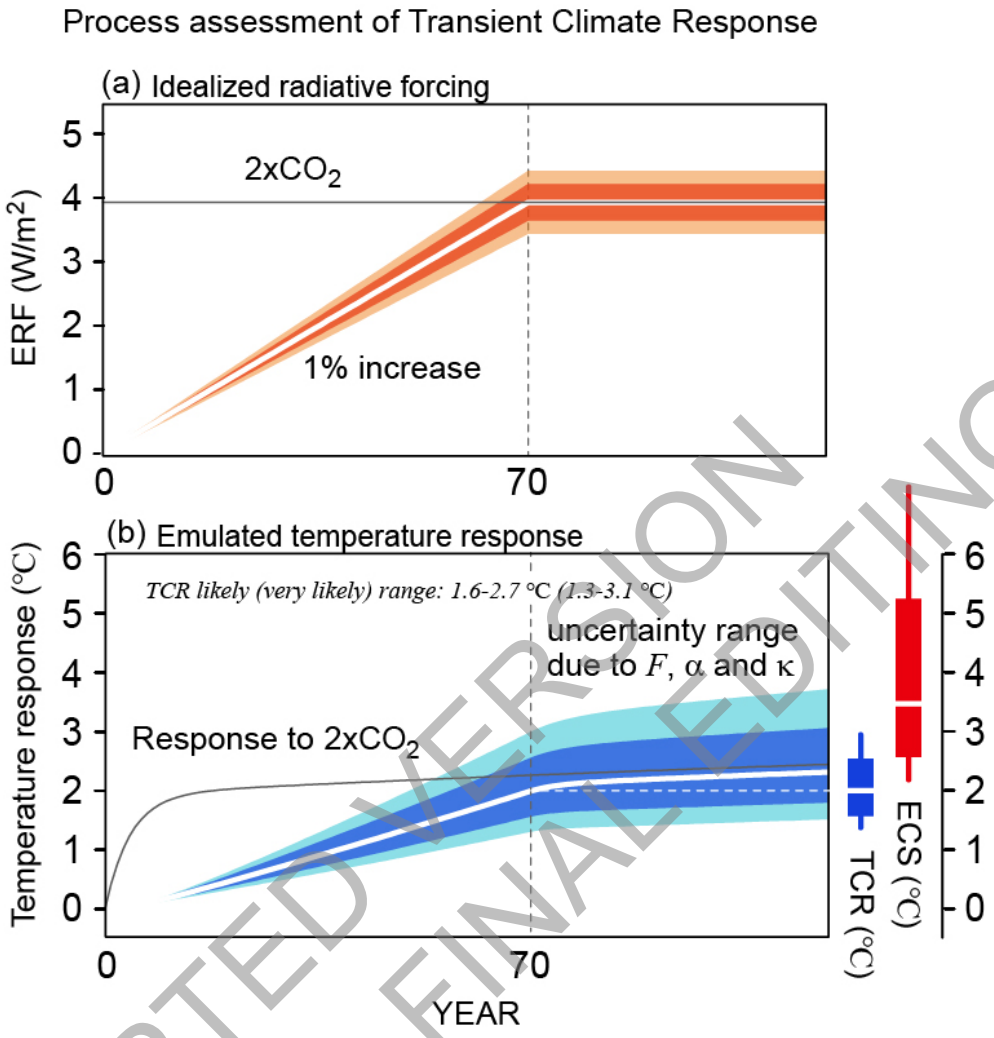

Figure 7.17: (a) Time evolution of the effective radiative forcing (ERF) to the CO_2 concentration increased by 1% per year until the year 70 (equal to the time of doubling) and kept fixed afterwards (white line). The *likely* and *very likely* ranges of ERF indicated by light and dark orange have been assessed in Section 7.3.2.1. (b) Surface temperature response to the CO_2 forcing calculated using the emulator with a given value of ECS, considering uncertainty in $\Delta F_{2\times CO2}$, α, and κ associated with the ocean heat uptake and efficacy (white line). The *likely* and *very likely* ranges are indicated by cyan and blue. For comparison, the temperature response to abrupt doubling of the CO_2 concentration is displayed by a grey curve. The mean, *likely* and *very likely* ranges of ECS and TCR are shown at the right (the values of TCR also presented in the panel). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

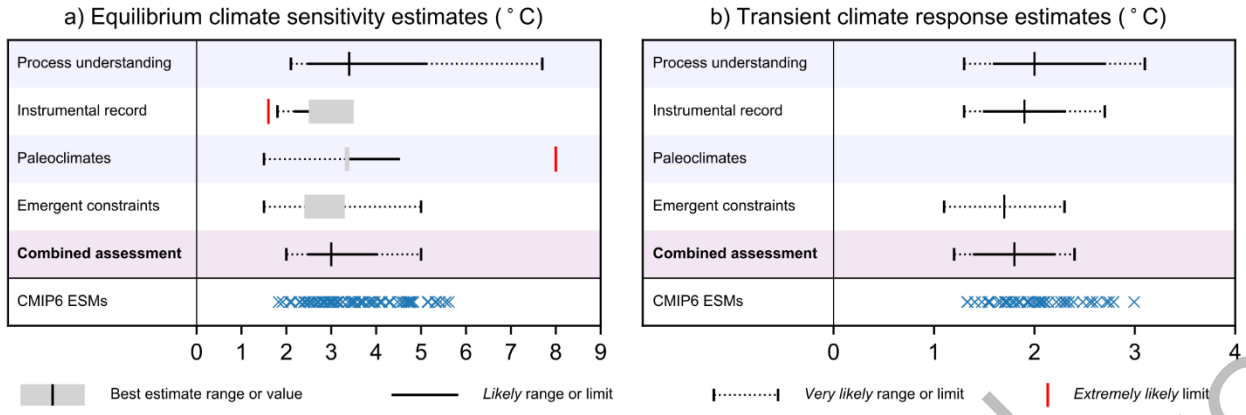

Figure 7.18: Summary of the equilibrium climate sensitivity (ECS) and transient climate response (TCR) assessments using different lines of evidence. Assessed ranges are taken from Tables 7.13 and 7.14 for ECS and TCR respectively. Note that for the ECS assessment based on both the instrumental record and paleoclimates, limits (i.e. one-sided distributions) are given, which have twice the probability of being outside the maximum/minimum value at a given end, compared to ranges (i.e. two tailed distributions) which are given for the other lines of evidence. For example, the *extremely likely* limit of greater than 95% probability corresponds to one side of the *very likely* (5% to 95%) range. Best estimates are given as either a single number or by a range represented by grey box. CMIP6 model values are not directly used as a line of evidence but presented on the Figure for comparison. ECS values are taken from Schlund et al. (2020) and TCR values from Meehl et al. (2020), see Supplementary Material 7.SM.4. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

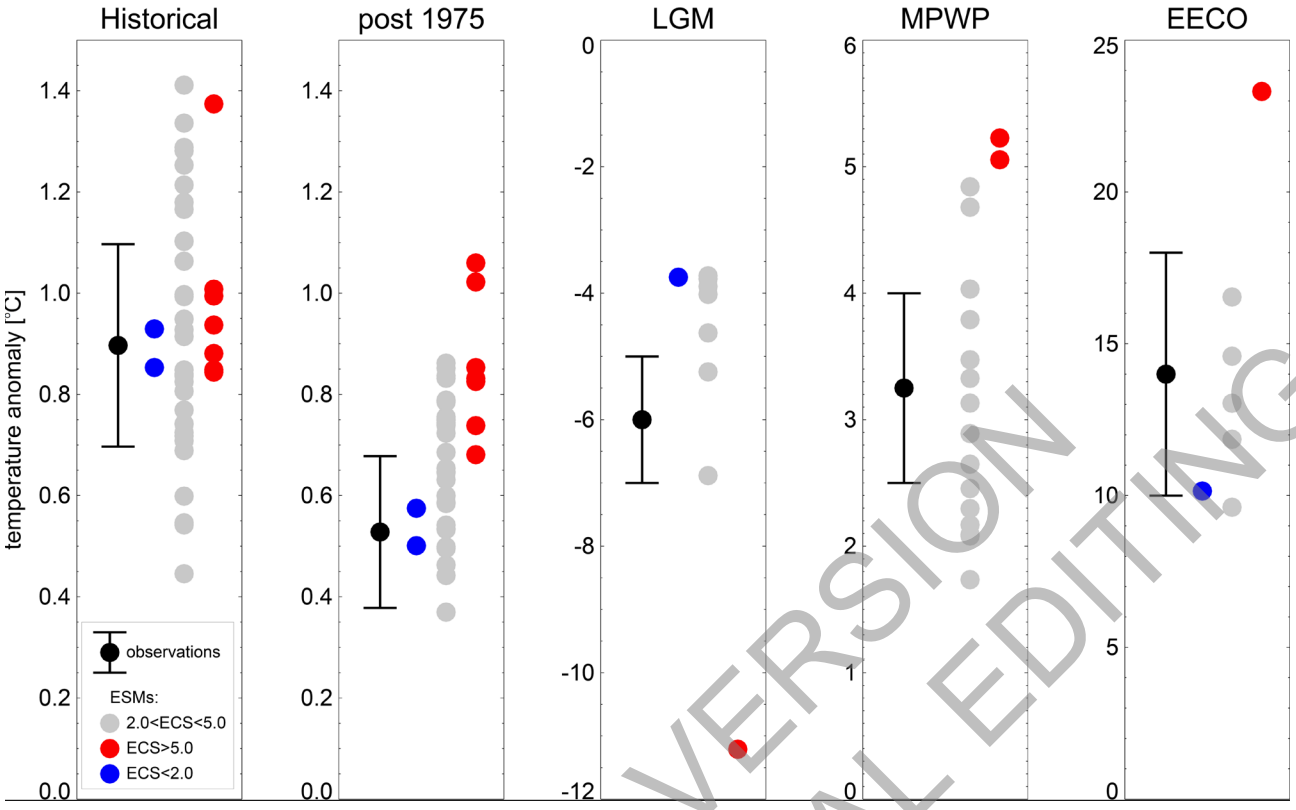

Figure 7.19: Global mean temperature anomaly in models and observations from 5 time periods. (a) Historical (CMIP6 models), (b) post 1975 (CMIP6 models), (c) Last Glacial Maximum (LGM; Cross-Chapter Box 2.1; PMIP4 models; (Kageyama et al., 2021; Zhu et al., 2021), (d) mid Pliocene warm period (MPWP; Cross-Chapter Box 2.4; PlioMIP models; Haywood et al., 2020; Zhang et al., 2021), (e) early Eocene climatic optimum (EECO; Cross-Chapter Box 2.1; DeepMIP models; Zhu et al., 2020; Lunt et al., 2021). Grey circles show models with ECS in the assessed *very likely* range; models in red have an ECS greater than the assessed *very likely* range (>5°C), models in blue have an ECS lower than the assessed *very likely* range (<2°C). Black ranges show the assessed temperature anomaly derived from observations (Chapter 2, Section 2.3). The Historical anomaly in models and observations is calculated as the difference between 2005–2014 and 1850–1900, and the post 1975 anomaly is calculated as the difference between 2005–2014 and 1975–1984. For the LGM, MPWP, and EECO, temperature anomalies are compared with pre-industrial (equivalent to CMIP6 simulation *piControl*). All model simulations of the MPWP and LGM were carried out with atmospheric CO_2 concentrations of 400 and 190 ppm respectively. However, CO_2 during the EECO is relatively more uncertain, and model simulations were carried out at either 1120ppm or 1680 ppm (except for the one high-ECS EECO simulation which was carried out at 560 ppm; Zhu et al., 2020). The one low-ECS EECO simulation was carried out at 1680 ppm. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

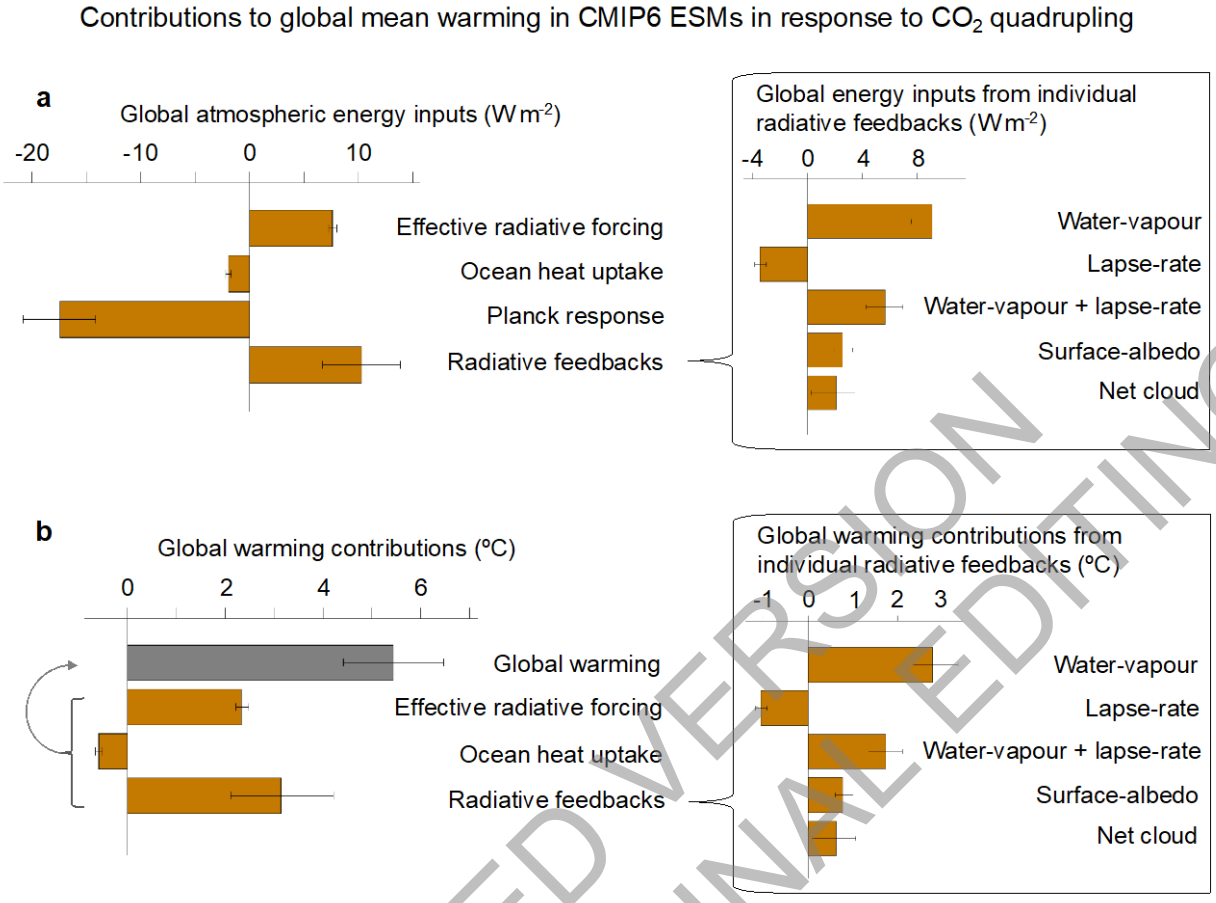

Figure 7.20: Contributions of effective radiative forcing, ocean heat uptake and radiative feedbacks to global atmospheric energy input and near-surface air temperature change at year 100 of *abrupt4xCO2* simulations of CMIP6 models. (a) The energy flux to the global atmosphere associated with the effective CO_2 forcing, global ocean heat uptake, Planck response, and radiative feedbacks, which together sum to zero. The inset shows energy input from individual feedbacks, summing to the total feedback energy input. (b) Contributions to net global warming are calculated by dividing the energy inputs by the *magnitude* of the global Planck response (3.2 W m^{-2} $°C^{-1}$), with the contributions from radiative forcing, ocean heat uptake, and radiative feedbacks (orange bars) summing to the value of net warming (grey bar). The inset shows warming contributions associated with individual feedbacks, summing to the total feedback contribution. Uncertainties show the interquartile range (25% and 75% percentiles) across models. Radiative kernel methods (see Section 7.4.1) were used to decompose the net energy input from radiative feedbacks into contributions from changes in atmospheric water vapour, lapse-rate, clouds, and surface albedo (Zelinka et al. (2020) using the Huang et al. (2017) radiative kernel). The CMIP6 models included are those analysed by Zelinka et al. (2020) and the warming contribution analysis is based on that of Goosse et al. (2018). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

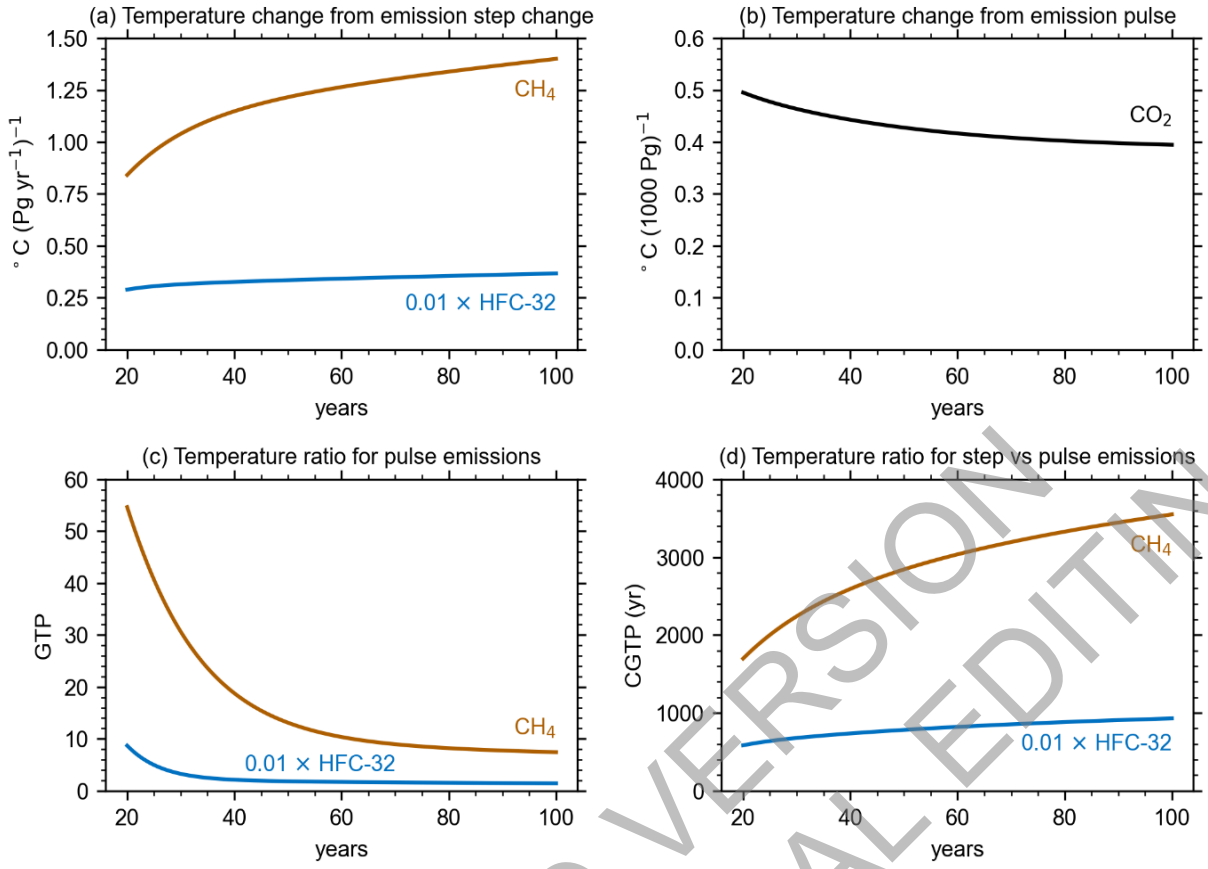

Figure 7.21: Emission metrics for two short-lived greenhouse gases: HFC-32 and CH_4, (lifetimes of 5.4 and 11.8 years). The temperature response function comes from Supplementary Material 7.SM.5.2. Values for non-CO_2 species include the carbon cycle response (Section 7.6.1.3). Results for HFC-32 have been divided by 100 to show on the same scale. (a) temperature response to a step change in short-lived greenhouse gas emission. (b) temperature response to a pulse CO_2 emission. (c) conventional GTP metrics (pulse vs pulse). (d) combined-GTP metric (step versus pulse). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

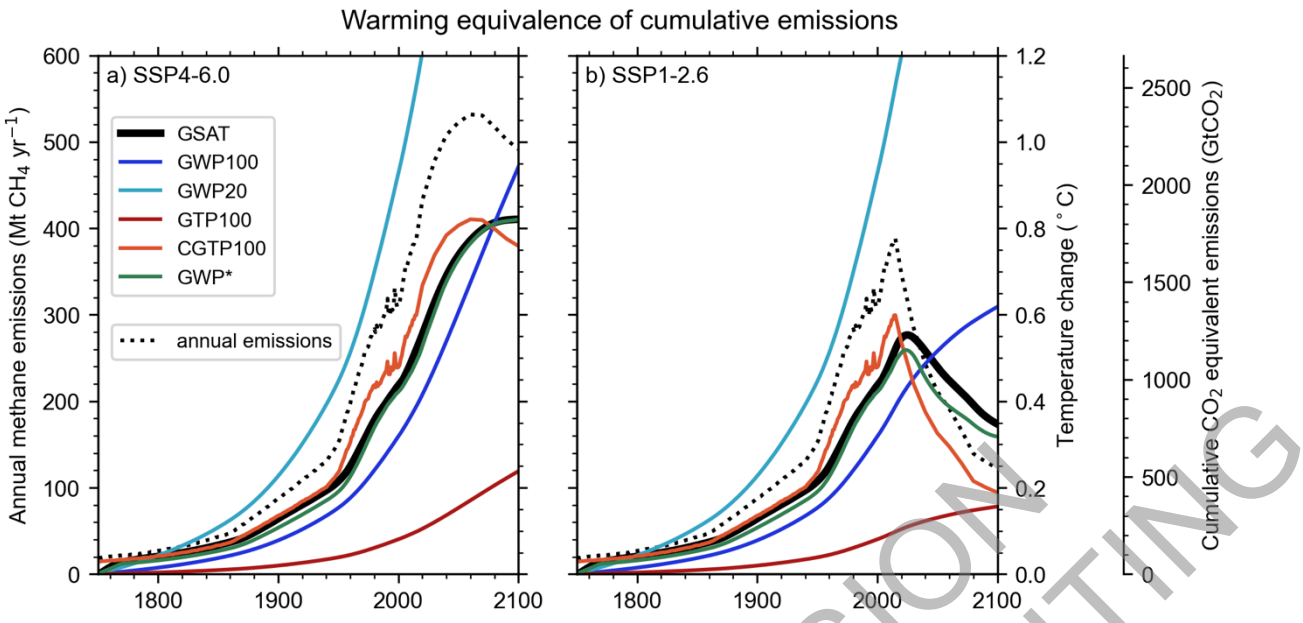
ACCEPTED VERSION SUBJECT TO FINAL EDITING



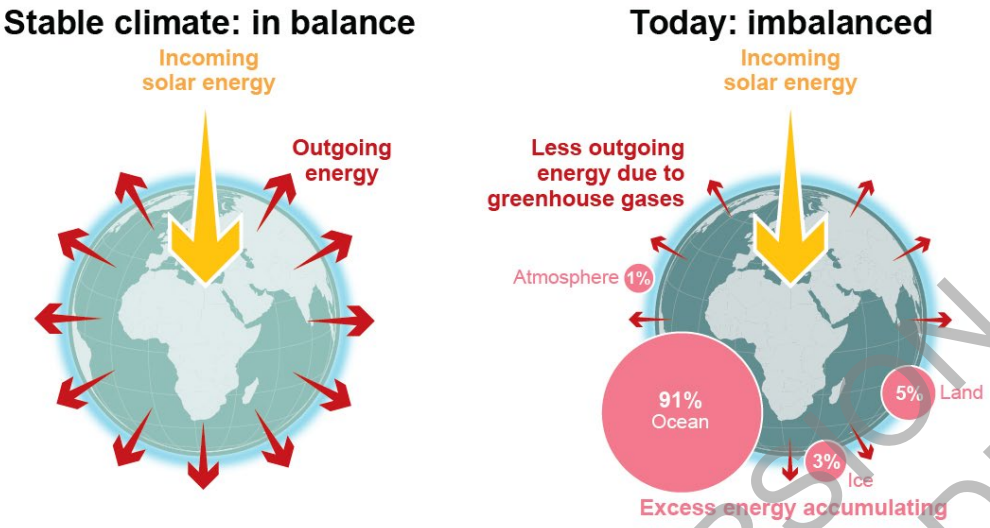


Figure 7.22: Explores how cumulative carbon dioxide equivalent emissions estimated for methane vary under different emission metric choices and how estimates of the surface temperature (GSAT) change deduced from these cumulative emissions compare to the actual temperature response computed with the two-layer emulator (solid black lines). Panels a) and b) show the SSP4-6.0 and SSP1-2.6 scenarios respectively. The panels show annual methane emissions as the dotted lines (left axis) from 1750–2100. The solid lines can be read as either estimates of GSAT change or estimates of the cumulative carbon dioxide equivalent emissions. This is because they are related by a constant factor, the TCRE. Thus, values can be read using either of the right hand axes. Emission metric values are taken from Table 7.15. The GWP* calculation is given in Section 7.6.1.4. The two-layer emulator has been calibrated to the central values of the report's assessment (see Supplementary Material 7.SM.5.2). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

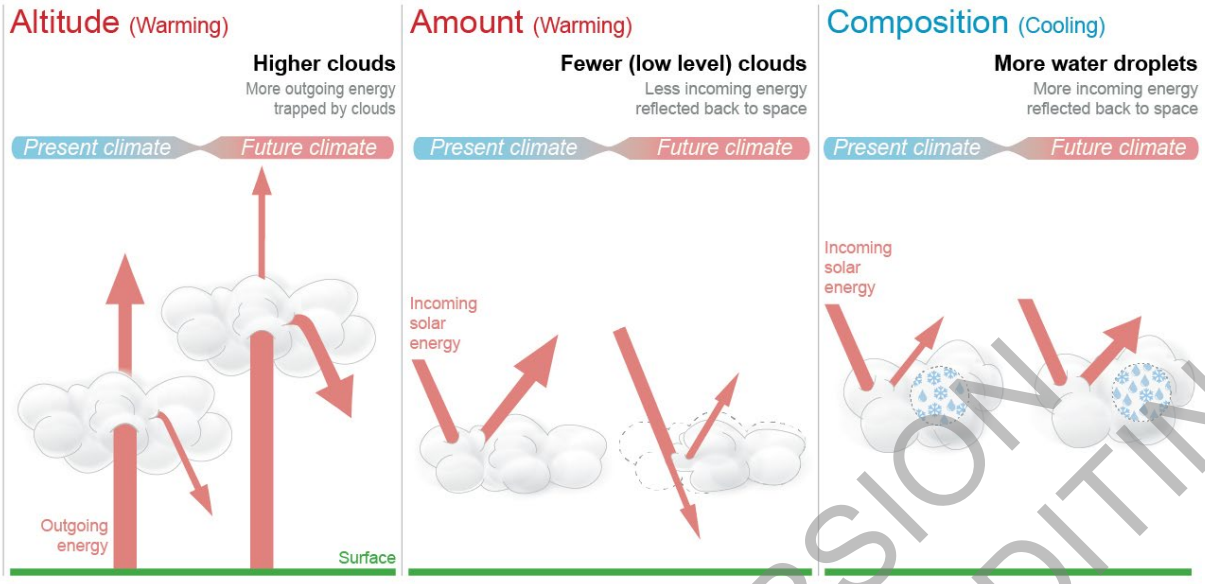
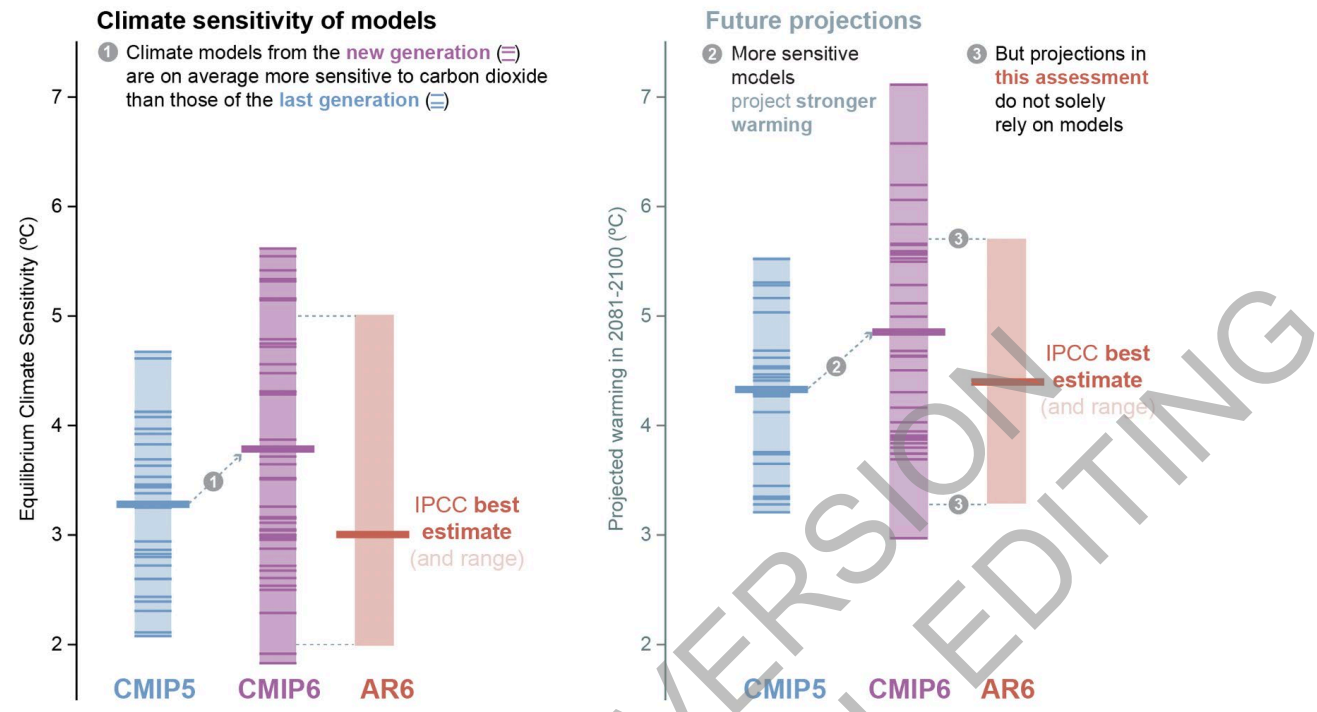
FAQ 7.1: The Earth's energy budget and climate change



Since at least 1970, there has been a persistent imbalance in the energy flows that has led to excess energy being absorbed by different components of the climate system.

FAQ 7.1, Figure 1: **The Earth's energy budget compares the flows of incoming and outgoing of energy that are relevant for the climate system.** Since the at least the 1970s, less energy is flowing out than is flowing in, which leads to excess energy being absorbed by the ocean, land, ice and atmosphere, with the ocean absorbing 91%.



ACCEPTED VERSION SUBJECT TO FINAL EDITING

FAQ 7.2: **What is the role of clouds in a warming climate?**
Clouds affect and are affected by climate change. Overall, scientists expect clouds to **amplify future warming**.

FAQ 7.2, Figure 1: **Interactions between clouds and the climate today and in a warmer future**. Global warming is expected to alter the altitude (left) and the amount (centre) of clouds, which will amplify warming. On the other hand, cloud composition will change (right), offsetting some of the warming. Overall clouds are expected to amplify future warming.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

FAQ7.3, Figure 1: Equilibrium climate sensitivity and future warming. (left) Equilibrium climate sensitivities for the current generation (sixth climate model intercomparison project, CMIP6) climate models, and the previous (CMIP5) generation. The assessed range in this report (AR6) is also shown. (right) Climate projections of CMIP5, CMIP6, and AR6 for the very high-emission scenarios RCP8.5, and SSP5-8.5, respectively. The thick horizontal lines represent the multi-model average and the thin horizontal lines the results of individual models. The boxes represent the model ranges for CMIP5 and CMIP6 and the range assessed in AR6.

7.SM.1 Effective Radiative Forcing

7.SM.1.1 Simplified expressions for greenhouse gases

In Section 7.3.2 and Table 7.5, simplified expressions for the stratospheric-temperature-adjusted radiative forcing (SARF) are used to convert greenhouse gas (GHG) concentrations to radiative forcing. AR5 (Myhre et al., 2013b) used relationships first introduced in Myhre et al. (1998), providing a logarithmic dependence of carbon dioxide (CO_2) SARF on CO_2 concentrations, and square root dependencies of methane (CH_4) and nitrous dioxide (N_2O) SARF on CH_4 and N_2O concentrations. The CH_4 and N_2O relationships accounted for band overlaps between these gases. These simplified expressions for SARF were revised in Etminan et al. (2016) using updated spectroscopic data. The most notable changes were a substantial revision in the methane RF of about +25% to account for previously neglected shortwave effects (Section 7.3.2.2) and inclusion of the mutual band overlap between carbon dioxide and nitrous oxide (Section 7.3.2.1). In Etminan et al. (2016), calculations from the Oslo line-by-line (LBL) radiative transfer model were conducted for 48 cases that co-varied concentrations of carbon dioxide, methane and nitrous oxide that spanned values from 180–2000 ppm CO_2, 340–3500 ppb CH_4 and 200–525 ppb N_2O. These ranges were selected to cover the minimum observed from ice core records during the Last Glacial Maximum to the maximum projected in the RCP8.5 scenario in the future (Meinshausen et al., 2011b; Riahi et al., 2011). Simplified relationships linking concentrations of CO_2, CH_4 and N_2O to the SARF from each gas, including overlaps, were provided from these 48 different cases that fit the original line-by-line results within a few percent.

A more accurate but complex functional fit was provided in Meinshausen et al. (2020) to the 48 Oslo LBL cases in Etminan et al. (2016). Two main advantages to the Meinshausen et al. (2020) fit are (i) the reduced error in the new fits to the original Oslo LBL results (maximum 0.11% for the CO_2 cases compared to 3.6% in Etminan et al. (2016)) and (ii) the extension of the valid range of the fits to CO_2 concentrations above 2000 ppm, which occurs in SSP5-8.5 in the future (though not RCP8.5). One drawback to the Meinshausen et al. (2020) fit compared to the original Etminan et al. (2016) fit is that the former is defined with respect to 1750 greenhouse gas concentrations, and requires a re-calculation of the coefficients to use baseline concentrations that are different from this, whereas the Etminan et al. (2016) fit is valid for any baseline concentration within their stated validity range (180–2000 ppm CO_2, 340–3500 ppb CH_4, 200–525 ppb N_2O). In general, AR6 and Chapter 7 in particular reports SARF and effective radiative forcing (ERF) relative to a 1750 baseline, negating this possible drawback, and so the Meinshausen et al. (2020) relationships are used for computing SARF and ERF throughout Chapter 7 and in Annex III. The relationships converting concentrations to SARF are shown in Table 7.SM.1. For halogenated greenhouse gases with concentrations in the ppt range, SARF remains a linear function of concentrations, as in AR5.

[START TABLE 7.SM.1 HERE]

Table 7.SM.1: Simplified expressions to compute radiative forcing (RF) from concentrations of greenhouse gases (Myhre et al., 1998; Meinshausen et al., 2020). C, N and M refer to concentrations of CO_2 in ppm, N_2O in ppb and CH_4 in ppb, respectively.

Gas	Radiative forcing (SARF) simplified expression	Coefficients
CO_2	$C_{\alpha_{\max}} = C_0 - \frac{b_1}{2a_1}$ $\alpha' = \begin{cases} d_1 - \frac{b_1^2}{4a_1}, & C > C_{\alpha_{\max}} \\ d_1 + a_1(C - C_0)^2 + b_1(C - C_0), & C_0 < C < C_{\alpha_{\max}} \\ d_1, & C < C_0 \end{cases}$ $\alpha_{N_2O} = c_1\sqrt{N}$ $\mathrm{SARF}_{CO_2} = (\alpha' + \alpha_{N_2O}) \cdot \ln\left(\frac{C}{C_0}\right)$	$a_1 = -2.4785 \times 10^{-7}$ W m^{-2} ppm^{-2} $b_1 = 7.5906 \times 10^{-4}$ W m^{-2} ppm^{-1} $c_1 = -2.1492 \times 10^{-3}$ W m^{-2} ppb$^{-1/2}$ $d_1 = 5.2488$ W m^{-2} $C_0 = 277.15$ ppm
N_2O	$\mathrm{SARF}_{N_2O} = (a_2\sqrt{C} + b_2\sqrt{N} + c_2\sqrt{M} + d_2) \cdot (\sqrt{N} - \sqrt{N_0})$	$a_2 = -3.4197 \times 10^{-4}$ W m^{-2} ppm^{-1} $b_2 = 2.5455 \times 10^{-4}$ W m^{-2} ppb^{-1}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

		$c_2 = -2.4357 \times 10^{-4}$ W m^{-2} ppb^{-1} $d_2 = 0.12173$ W m^{-2} ppb$^{-1/2}$ $N_0 = 273.87$ ppb
CH_4	$\mathrm{SARF}_{CH_4} = \left(a_3\sqrt{M} + b_3\sqrt{N} + d_3\right) \cdot \left(\sqrt{M} - \sqrt{M_0}\right)$	$a_3 = -8.9603 \times 10^{-5}$ W m^{-2} ppb^{-1} $b_3 = -1.2462 \times 10^{-4}$ W m^{-2} ppb^{-1} $d_3 = 0.045194$ W m^{-2} ppb$^{-1/2}$ $M_0 = 731.41$ ppb
Halogenated compounds and other minor GHGs	$\mathrm{SARF}_X = e_X(X - X_0)$	X and X_0 in ppb e_X is radiative efficiency (W m^{-2} ppb^{-1}) (Table 7.SM.7)

[END TABLE 7.SM.1 HERE]

7.SM.1.2 Effective radiative forcing from a doubling of CO_2

In Section 7.3.2.1, the ERF from a doubling of CO_2 ($\Delta F_{2\times CO2}$ = 3.93 W m^{-2}) is defined relative to 1750 CE concentrations of CO_2 assessed in Chapter 2 (C_0 = 278.3 ppm) and N_2O (N_0 = 270.1 ppb) using the Meinshausen et al. (2020) fits (Table 7.SM.1) to calculate SARF of 3.75 W m^{-2} and then adding an additional 5% for tropospheric adjustments (Section 7.3.2.1; Table 7.3). Using the Etminan et al. (2016) fits with the same baseline concentrations (C_0 = 278.3 ppm, N_0 = 270.1 ppb) results in a SARF of 3.80 W m^{-2} and an ERF of 3.99 W m^{-2} (Table 7.SM.2). The simplified expressions are used as no specific line-by-line experiment was performed for a doubling of CO_2 from about 1750 concentrations in Etminan et al. (2016).

Alongside the choice of simplified expression, the baseline CO_2 and N_2O concentrations also has an impact on the SARF and ERF from a doubling of CO_2 (Table 7.SM.2). Using 1850 CE baselines results in ERF values that are close, but not exactly the same, as using 1750 CE baselines (Table 7.SM.2). Using a present-day baseline results in estimates of SARF and ERF from a doubling of CO_2 that are about 1% greater than the 1750 or 1850 values (Table 7.SM.2). The 1850 baseline is significant as it the reference pre-industrial state for CMIP6 experiments, including the *abrupt4xCO2* and *1pctCO2* experiments used to estimate ECS and TCR from climate models. It should be noted that the *1pctCO2* experiment design relies on a logarithmic increase in CO_2 SARF with concentration to estimate TCR (Gregory et al., 2015), and both the Etminan et al. (2016) and Meinshausen et al. (2020) SARF formulas are super-logarithmic with increasing CO_2 concentrations.

[START TABLE 7.SM.2 HERE]

Table 7.SM.2: Computed values of the SARF of a doubling of CO_2 using the relationships in Etminan et al. (2016) and Meinshausen et al. (2020), and the ERF from a doubling of CO_2 (assessed to be SARF + 5% in Section 7.3.2.1), from different baseline concentrations of CO_2 and N_2O, and compared to SARF in AR5.

7.SM.1.3 Historical (1750-2019) effective radiative forcing time series

7.SM.1.3.1 Best estimate historical time series

The historical ERF time series describes how the best estimates of changes in climate drivers translates to ERF for 1750 to 2019. The time-evolution of ERF is reported separately for CO_2, CH_4, N_2O, other well-mixed greenhouse gases (WMGHGs), ozone, stratospheric water vapour from methane oxidation, contrails and aviation-induced cirrus, aerosol-radiation interactions, aerosol-cloud interactions, light-absorbing particles on snow and ice, land-use change, volcanic, and solar. The contributions from 49 halogenated GHGs comprising the "other well-mixed greenhouse gases" category are further reported individually. Data is published in Annex III.

For CO_2, CH_4 and N_2O, the SARFs are calculated using time-dependent best-estimate concentrations of these gases from Chapter 2 using the formulae in Table 7.SM.1 and using concentrations from Chapter 2 in 1750 CE as baselines (C_0 = 278.3 ppm, N_0 = 270.1 ppb, M_0 = 729.2 ppb). Tropospheric adjustments of +5% for CO_2, –14% for CH_4 and +7 % are then added to these SARF values to produce ERF (Section 7.3.2). For 49 halogenated greenhouse gases, concentration changes since 1750 are used combined with radiative efficiencies detailed in Table 7.SM.7 to derive SARF (Table 7.SM.1). Accounting for tropospheric adjustments adds +13% and +12% to CFC-11 and CFC-12 respectively when moving from SARF to ERF. No tropospheric adjustments are assumed for other halogenated species (Section 7.3.2.4).

For historical ozone forcing, the time series from 1750 to 2020 from Skeie et al. (2020) is adopted, using the multi-model mean ERF from six independent Earth System and chemistry-climate models (BCC-ESM1, CESM2-WACCM6, GFDL-ESM4, GISS-E2-1-H, MRI-ESM2-0 and Oslo-CTM3) that used CMIP6 precursor emissions and interactively calculated ozone burdens using full stratospheric and tropospheric chemistry schemes. From the original 12 models reporting results in Skeie et al. (2020), CNRM-CM6, CNRM-ESM2-1 and E3SM1-0 were excluded as they do not include full stratospheric and tropospheric chemistry, only the first out of the similar models CESM2-WACCM6 and CESM2-CAM6 were used, the input4MIPs forcing estimate (Checa-Garcia et al., 2018) was excluded as it did not use CMIP6 precursor emissions, and UKESM-1-0-LL was excluded for having implausible time evolutions of stratospheric ozone that resulted in negative total ozone ERF estimates for 2010 relative to 1850. The extrapolations for the 1750–1850 and 2010–2020 periods (run beyond 2014 using SSP2-4.5) came from a single model (Oslo-CTM3) and results were used up to and including 2019. Stratospheric water vapour from methane oxidation is treated a linear scaling of the methane ERF and scaled to the 1750–2019 assessment of 0.05 W m^{-2} (Section 7.3.2.6).

Several forcing categories (contrails, aviation-induced cirrus aerosols, and black carbon on snow) are derived from global annual emissions totals of short-lived climate forcers. For the best estimate of historical emissions from 1750 to 2019, the 11 September 2020 version of the Community Emissions Data System (CEDS) is used (Hoesly et al., 2018), obtained from https://doi.org/10.5281/zenodo.4025316. CEDS provides emissions of black carbon (BC), organic carbon (OC), sulphur dioxide (SO_2), ammonia (NH_3), nitrogen oxides (NOx), carbon monoxide (CO) and non-methane volatile organic compounds (NMVOC) from the fossil fuel, industrial and agricultural sectors. Biomass burning emissions are used from the BB4CMIP dataset (also used for CMIP6 model integrations, from Van Marle et al. (2017)), aggregated into global annual totals. The SSP2-4.5 scenario projection from BB4CMIP is used for 2015-2019.

ERF from contrails and aviation-induced cirrus uses global aviation NOx emissions as a predictor of aviation

ACCEPTED VERSION SUBJECT TO FINAL EDITING

activity following Smith et al. (2018a), and scaled to the 2018 ERF best estimate of 0.0574 W m^{-2} from Lee et al. (2020).

ERF from aerosol-radiation interactions (ERFari) was calculated by converting emissions of BC, OC, SO_2 (representing sulphate aerosol) and NH_3 (representing nitrate aerosol) to forcing using CMIP5-era ACCMIP multi-model mean contributions for each species from Myhre et al. (2013a) and scaled to obtain the assessment of –0.3 W m^{-2} for ERFari which is applied to the 2005–2014 decade. ERFari was calculated using a simple linear relationship to emissions of BC, OC, SO_2 and NH_3 (E_{BC}, E_{OC}, E_{SO2}, E_{NH3}):

$$\mathrm{ERFari} = \beta_{\mathrm{BC}}E_{\mathrm{BC}} + \beta_{\mathrm{OC}}E_{\mathrm{OC}} + \beta_{\mathrm{SO2}}E_{\mathrm{SO2}} + \beta_{\mathrm{NH3}}E_{\mathrm{NH3}} \qquad \textit{Equation 7.SM.1.1}$$

The β coefficients are selected to represent ERFari contributions of +0.3 W m^{-2} from black carbon, –0.4 W m^{-2} from sulphate, –0.09 W m^{-2} from organic carbon and –0.11 W m^{-2} from nitrate over the 2005–2014 decade, which translates to radiative efficiencies of β_{BC} = 50.8 mW yr m^{-2} MtC^{-1}, β_{OC} = –6.21 mW yr m^{-2} MtC^{-1}, β_{SO2} = –3.62 mW yr m^{-2} $MtSO_2^{-1}$, and β_{NH3} = –2.08 mW yr m^{-2} $MtNH_3^{-1}$. Newer CMIP6 model results were not used as fewer model results are available and the complexity of aerosol schemes and internal mixing in these models makes attribution of aerosol forcing to precursors more difficult than in CMIP5-era models.

ERF from aerosol-cloud interactions (ERFaci) is modelled as a logarithmic function of emissions of SO_2, BC and OC following Smith et al. (2018a):

$$\mathrm{ERFaci} = -\beta \ln(1 + E_{\mathrm{SO2}}/s_{\mathrm{SO2}} + (E_{\mathrm{BC+OC}}/s_{\mathrm{BC+OC}})) \qquad \textit{Equation 7.SM.1.2}$$

Eq. (7.SM.1.2) is based on the offline model of Ghan et al. (2013) using a functional form developed by Stevens (2015) with the inclusion of a carbonaceous aerosol term than can influence ERFaci. Eq. (7.SM.1.2) was tuned to 11 CMIP6 models that provided historical time-varying (1850-2014) ERFaci estimates and a parameter set of β, s_{SO2} and s_{BC} was obtained for each CMIP6 model. The parameter tunings from these 11 models were used to generate distributions using kernel density estimates from which 100,000 sample members were drawn and 100,000 candidate ERFaci time series were produced. The best estimate ERFaci time series is taken from the median of this 100,000-member ensemble, and then scaled to the assessed ERFaci of –1.0 W m^{-2} for 1750 to 2005–2014.

ERF from light-absorbing particles on snow is linear with BC emissions and scaled to the 1750-2019 ERF assessment of 0.08 W m^{-2}.

ERF from land-use change is broken down into an albedo component and an irrigation component. The albedo component follows the historical ERF time series from Ghimire et al. (2014) from 1700 to 2005, and is extended forward to 2019 using cumulative land-use related CO_2 emissions from the SSP Historical and SSP2-4.5 scenarios. This follows the treatment in Smith et al. (2018a) and assumes that land-use related CO_2 is closely related to deforestation and albedo change. The 1750-2019 assessment of –0.15 W m^{-2} is then applied to the time series. The ERF from irrigation, assessed to be –0.05 W m^{-2} for 1750–2019 (Sherwood et al., 2018), scales with the albedo component.

All anthropogenic components of the ERF described above are expressed relative to a 1750 baseline.

Natural forcings comprise solar changes and volcanic eruptions (forcing from galactic cosmic rays is assessed to be negligible, Section 7.3.4.5). Volcanic ERF is derived from stratospheric aerosol optical depth (SAOD) using a conversion of –20 × ΔSAOD (Section 7.3.4.6), or ERF = –20 × SAOD + 0.2582 W m^{-2} using absolute SAOD where SAOD is nominally taken at 550 nm wavelength. The SAOD conversion to ERF is expressed as an anomaly in SAOD relative to the 500 BCE to 1749 CE mean, so that the mean volcanic ERF for 500 BCE to 1749 CE is zero. This is in order that the long-term mean GSAT change from pre-industrial volcanic forcing alone is zero, avoiding a spurious cooling effect when applying the volcanic

ACCEPTED VERSION SUBJECT TO FINAL EDITING

time series from 1750 onwards to projections in a climate emulator (e.g. Section 7.SM.2). This convention means that volcanically quiescent years experience a volcanic ERF of up to +0.2 W m^{-2} (even volcanically quiescent years have some level of background stratospheric aerosol, so volcanic ERFs approaching the offset value of +0.2582 W m^{-2} are not seen). CMIP6 uses a similar prescription for volcanic forcing in ESMs, by applying a constant background climatology of SOAD for *piControl* and *ScenarioMIP* runs that is based on the historical (1850–2014) mean SAOD (Eyring et al., 2016).

The SAOD time series is derived from a composite of three datasets: eVolv v3 (Toohey and Sigl, 2017) for 500 BCE to 1900 CE, CMIP6 for 1850 to 1989, and GloSSAC v2 (Kovilakam et al., 2020) from 1979 to 2018. SAOD from GloSSAC v2 is reported at a wavelength of 525 nm and has been converted to 550 nm using an Ångström exponent of –2.33 (Kovilakam et al., 2020). The 2018 volcanic ERF is repeated for 2019. The 1850 to 1900 overlap is performed by linearly ramping down the eVolv v3 dataset and linearly ramping up the CMIP6 dataset. The CMIP6 and GloSSAC v2 data are ramped over the 1979 to 1989 period. In both cases the correspondences between overlapping periods is good.

Solar ERF is calculated using the change in total solar irradiance (TSI) where TSI is taken from the ^{14}C SATIRE-M reconstruction from PMIP4 (Jungclaus et al., 2017) and converted to ERF using ¼ × 0.71 × 0.72 × ΔTSI (Section 7.3.4.4). The baseline for TSI is the mean TSI from 6754 BCE to 1744 CE, which encompasses complete solar cycles in the proxy reconstructions before 1750.

Aerosols and solar ERFs in 2019 both differ from the headline assessments given in Sections 7.3.3 and 7.3.4.4 respectively. For aerosols, the assessment in Section 7.3.3 of –1.3 ± 0.7 W m^{-2} is valid for 1750 to about 2014, as less evidence is available for trends in how aerosol forcing has evolved in more recent years. The emissions-based time series provides a best-estimate aerosol ERF for 1750–2019 of –1.06 W m^{-2}, less negative than the 1750–2014 assessment, owing to a recent decline in precursor emissions since around 2005 from the CEDS dataset and supported by other studies (Paulot et al., 2018; Kanaya et al., 2020). For solar ERF, the Chapter 7 assessment of +0.01 ± 0.07 W m^{-2} is for the 6754 BCE to 1744 CE pre-industrial period to the 2009–2019 solar cycle. The single year 2019, corresponding to a solar minimum, has a solar ERF of –0.02 W m^{-2} relative to this pre-industrial baseline.

7.SM.1.3.2 Uncertainties in the historical best estimate time series

The uncertainty in the historical ERF time series was generated with a 100,000-member Monte Carlo ensemble. The forcing components where uncertainty ranges are assumed to be symmetric and Gaussian in their assessments in Section 7.3 have a scale factor drawn from a Gaussian distribution with mean of unity and 5–95% uncertainty range determined as a fraction of the best estimate ERF. The forcing components with symmetric uncertainty ranges are CO_2 (fractional 5–95% uncertainty 0.12 of the best estimate), CH_4 (0.20), N_2O (0.16), halogenated gases (0.19 on the basis that the majority are "long-lived"), ozone (0.50), stratospheric water vapour (1.00), land use change (0.50) and volcanic (0.25). Contrails (and aviation-induced cirrus) and light-absorbing particles on snow and ice have asymmetric uncertainty ranges and the fractional uncertainty was determined by considering ranges below and above the best estimate separately, by dividing the 5th percentile by the best estimate to derive the lower uncertainty range and the 95th percentile by the best estimate to determine the upper range, treating them as two halves of a Gaussian distribution. In each ensemble member the sampled uncertainty scale factor for each component of the forcing is applied to the whole time series.

For aerosols, the ERFari and ERFaci are treated independently. ERFari uncertainty is developed by sampling the radiative efficiency coefficients β_{BC}, β_{OC}, β_{SO2} and β_{NH3} in Eq. (7.SM.1.1) as Gaussian distributions with 5–95% ranges uncertainties of 0.67, 0.78, 0.50 and 0.44, yielding contributions to ERFari of +0.3 ± 0.2 W m^{-2} for BC, –0.4 ± 0.2 W m^{-2} for sulphate, –0.09 ± 0.07 W m^{-2} for OC and –0.11 ± 0.05 W m^{-2} for nitrate for the 2005–2014 mean with respect to 1750. Each precursor species is sampled independently and the historical emissions from the CEDS database are used to generate the time series of ERFari. For ERFaci, the 100,000 generated time series described in Section 7.SM.1.3 are used with one additional step to scale each ERFaci candidate time series to a 2005–2014 mean ERFaci of –1.0 ± 0.7 W m^{-2} with respect to 1750. This

ACCEPTED VERSION SUBJECT TO FINAL EDITING

effectively rescales the β coefficients in each ensemble member in Eq. (7.SM.1.2) .

The 5–95% range of anthropogenic ERF of 1.96–3.48 W m^{-2} (Table 7.8) for 1750–2019 is determined from the 5th and 95th percentiles of the year 2019 anthropogenic ERF in this 100,000 member ensemble.

For solar forcing, a 0.50 fractional uncertainty was applied to the amplitude of the solar cycle, and a linear 1750 to 2019 trend of ±0.07 W m^{-2} (5–95%) range was added to this to represent the uncertainty in the change in the underlying solar forcing (Section 7.3.4.4).

7.SM.1.4 SSP and RCP effective radiative forcing time series

A similar method to the process described in Section 7.SM.1.3 is used to derive the ERF time series in RCP and SSP scenarios to 2500 (Annex III; Figure 4.36; Chapter 6; Chapter 9). From 1750 to 2014 the best estimate and uncertainty SSP projections ERF time series and the historical ERF time series described are identical. The SSPs diverge from each other, and from the historical best estimate, in 2015. For SSPs, the set of eight Tier 1 and Tier 2 scenarios defined by *ScenarioMIP* are assessed (SSP1-1.9, SSP1-2.6, SSP4-3.4, SSP5-3.4-over, SSP2-4.5, SSP4-6.0, SSP3-7.0 and SSP5-8.5). In addition two variants of SSP3-7.0 used primarily by AerChemMIP are presented: one where short-lived climate forcers are set to emissions factors consistent with strong air-quality controls that are broadly consistent with SSP1-levels of mitigation, SSP3-7.0-lowNTCF (Collins et al., 2017), plus a further variant of SSP3-7.0-lowNTCF that also takes into account methane mitigation alongside other short-lived forcers, SSP3-7.0-lowNTCFCH4 (Allen et al., 2021).

For 2015 to 2020, a linear transition between the concentrations of well-mixed greenhouse gases provided by Chapter 2 and the SSP greenhouse gas concentrations from Meinshausen et al. (2020) is performed. From 2020 onwards concentration projections from Meinshausen et al. (2020) are used. The correspondence between the Chapter 2 assessed time series and Meinshausen et al. (2017) dataset used for the CMIP6 *historical* experiment is good, with a maximum difference of 0.6% from 1850-2014 for the main three greenhouse gases and 1.4% for N_2O in 1750 (the slight 1750 concentration differences affects the $2\times CO_2$ forcing in the third decimal place; see Table 7.SM.2).

For purely emissions-based forcing estimates (aerosols, contrails and aviation-induced cirrus, and black carbon on snow), a similar 5-year transition between 2015 and 2020 is performed for fossil fuel, industrial and agricultural emissions. The best-estimate historical emissions to 2019 are provided in the 11 September 2020 version of the CEDS database (https://doi.org/10.5281/zenodo.4025316) and the SSP scenario projections used v5.1 of the RCMIP dataset (obtained from https://doi.org/10.5281/zenodo.4589756; Nicholls et al., (2020)) that provides consolidated regional and sectoral annual emissions totals from the CMIP6 SSP emissions datasets (Velders et al., 2015; Gidden et al., 2019; Meinshausen et al., 2020). Biomass burning emissions are used from the SSP emissions projections from Van Marle et al. (2017). The same parameter sets from the historical ERF estimate and 100,000 member Monte Carlo ensemble are used to derive the future ERFs from aerosols, contrails (and aviation-induced cirrus) and black carbon on snow, using the SSP emissions projections.

Future ozone forcing for SSP projections differs from the historical treatment and is based on emissions of short-lived forcers and concentrations of ozone-depleting greenhouse gases (Section 6.4). To generate the best-estimate projection, the historical time series in Skeie et al. (2020) is matched to emissions-driven estimates of ozone ERF from AerChemMIP models (Thornhill et al., 2021b), displayed in Table 7.SM.3 that sums to +0.37 W m^{-2} for 1850 to 2014. There is a temperature-dependent feedback on ozone ERF of –0.037 W m^{-2} °C^{-1} for CMIP historical runs (this differs from the assessment in Section 6.4 of –0.064 W m^{-2} °C^{-1} which is based on *abrupt4xCO2* experiments, as it includes the effects of the lightning NOx and BVOC feedbacks that act to reduce the magnitude of the temperature-ozone feedback (Thornhill et al., 2021a)). As five of the six Earth System Models run in Skeie et al. (2020) considered in the ERF ozone assessment were CMIP historical runs (all except Oslo-CTM3) and simulated the increase in historical GSAT over time, they implicitly included this feedback and as such the –0.037 W m^{-2} °C^{-1} feedback it is subtracted from the transient ozone ERF in these five models, using GSAT time series assessed in Chapter 2, to produce a "zero-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

feedback" estimate of ozone forcing from 1850 to 2014 of +0.47 W m^{-2}. To apply the emissions precursors to the overall time series, they are scaled by a factor of 1.27, derived from a ratio of the zero feedback estimate from Skeie et al. (2020) to the best estimate from the sum of precursors from Thornhill et al. (2021b) (0.47/0.37) to produce radiative efficiencies for each species (Table 7.SM.3).

[START TABLE 7.SM.3 HERE]

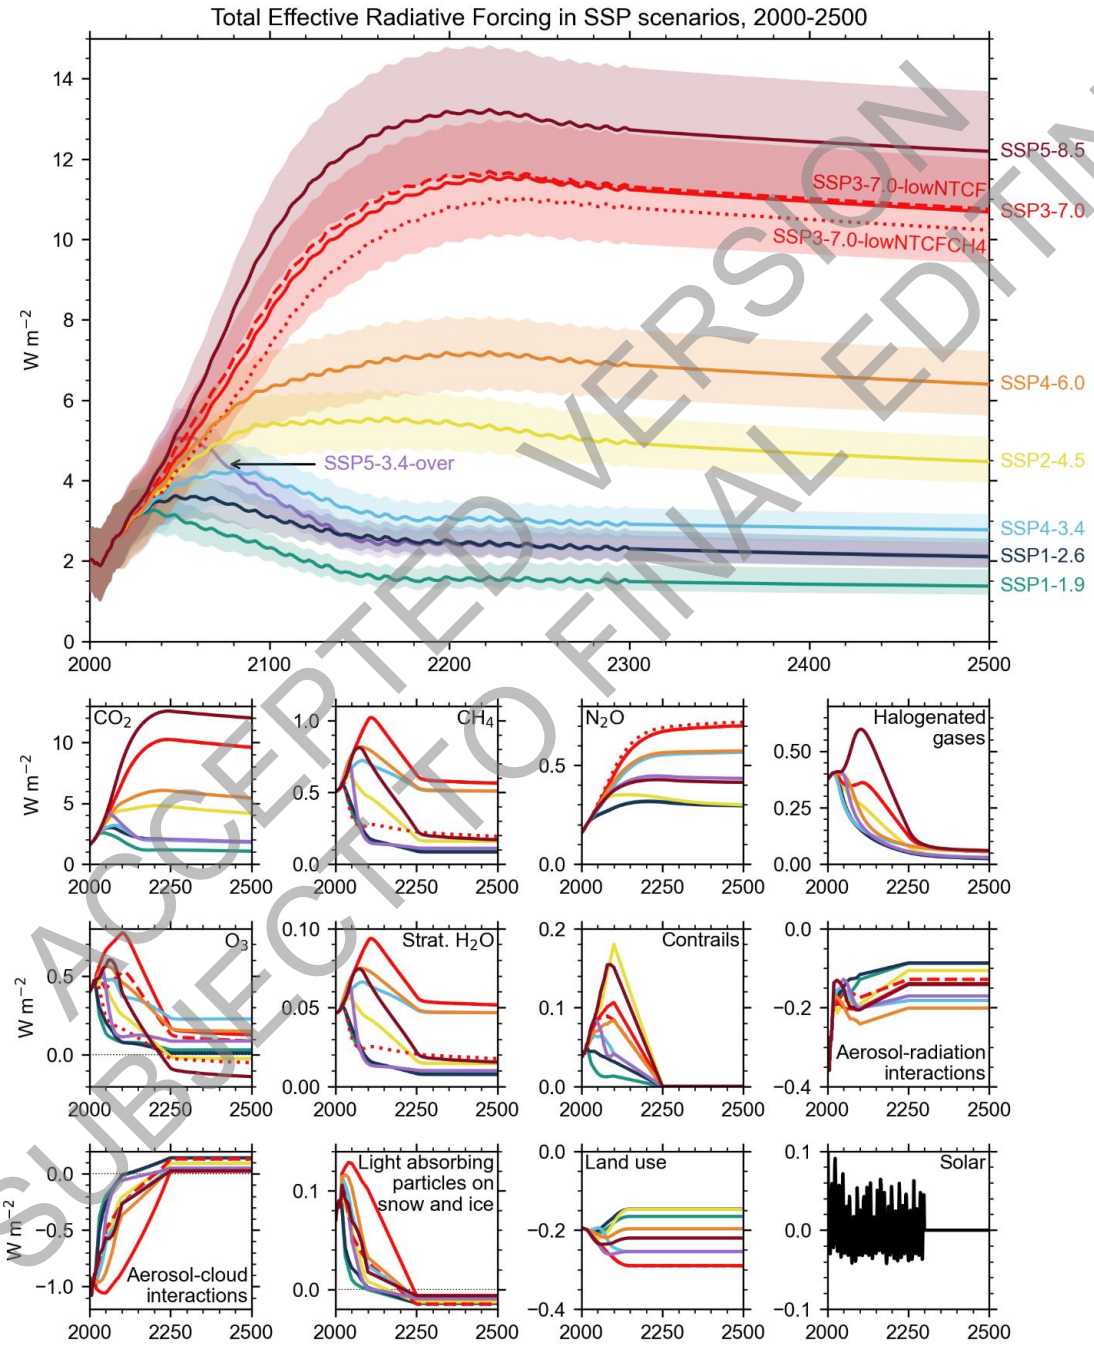
Table 7.SM.3: ERF from ozone precursors in AerChemMIP experiments (Thornhill et al., 2021b), and radiative efficiencies derived for emissions-based SSP pathways. The contributions for CO + NMVOC are not separated in Thornhill et al. (2021b) so the ratio of CO : NMVOC from CMIP5 ACCMIP experiments is used (Stevenson et al., 2013). "Concentrations" of ozone-depleting halocarbons (ODHs) are expressed in equivalent effective stratospheric chlorine in ppt.

species	Contribution to ozone ERF 1850-2014, W m^{-2} (Stevenson et al., 2013; Thornhill et al., 2021b)	Scale factor to reproduce 1850-2014 ozone ERF in Skeie et al. (2020), after subtracting temperature feedback	Radiative efficiency for ozone ERF
CH_4	+0.14 ± 0.05	1.27	β_{CH4} = 0.175 ± 0.062 mW m^{-2} ppb^{-1}
N_2O	+0.03 ± 0.02		β_{N2O} = 0.710 ± 0.062 mW m^{-2} ppb^{-1}
Ozone-depleting halocarbons (ODH)	–0.11 ± 0.10		β_{ODH} = –0.125 ± 0.113 mW m^{-2} ppt^{-1}
CO	+0.07 ± 0.06		β_{CO} = 0.155 ± 0.131 mW m^{-2} $MtCO^{-1}$ yr
NMVOC	+0.04 ± 0.04		β_{NMVOC} = 0.329 ± 0.328 mW m^{-2} $MtNMVOC^{-1}$ yr
NOx	+0.20 ± 0.11		β_{NOx} = 1.797 ± 0.983 mW m^{-2} $MtNO_2$ yr^{-1}
Sum	+0.37 ± 0.18	+0.47 ± 0.24 W m^{-2} (total ozone ERF)	

[END TABLE 7.SM.3 HERE]

The future ozone ERF is then derived as

$$ERF_{O3} = \beta_{CH4}\Delta C_{CH4} + \beta_{N2O}\Delta C_{N2O} + \beta_{ODH}\Delta C_{ODH} + \beta_{CO}\Delta E_{CO} + \beta_{NMVOC}\Delta E_{NMVOC} + \beta_{NOx}\Delta E_{NOx} - f \cdot \Delta T \quad \textit{Equation 7.SM.1.3}$$



where C_{CH4} and C_{N2O} are concentrations of CH_4 and N_2O in ppb, C_{ODH} is the equivalent effective stratospheric chlorine from halogenated compounds expressed in ppt (Newman et al., 2007), and E_{CO}, E_{NMVOC} and E_{NOx} are annual emissions in Mt yr^{-1} (NOx expressed in units of $MtNO_2$), f = –0.037 W m^{-2} $°C^{-1}$ and ΔT represents GSAT anomaly. This configuration is run iteratively, with other best-estimate forcings, in the two-layer emulator (Section 7.SM.2) with the Section 7.5.5 best-estimate assessments of equilibrium climate sensitivity (ECS, 3.0°C) and transient climate response (TCR, 1.8°C) until convergence is achieved.

ERF from land use change scales with cumulative emissions of land-use-related CO_2 emissions following the end of the historical period.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Volcanic forcing is set to a ten-year linear ramp down to zero from 2014 to 2024, following the CMIP6 ScenarioMIP protocol (Eyring et al., 2016). Solar forcing uses the CMIP6 future TSI variation (Matthes et al., 2017) which provides projections to 2299, and is set to zero from 2300. For Figure 4.36 and Annex III, ERF time series for the RCP scenarios are produced using emissions and concentrations from Meinshausen et al. (2011b) using the same methods, present-day forcing best estimates, and uncertainty ranges described above, with the difference that scenarios start to diverge in 2005 and a 15-year ramp from 2005 to 2020 from historical emissions or concentrations to the future RCP projections is performed.

7.SM.2 Two-layer energy balance model for climate emulation

7.SM.2.1 Emulator definition

The two-layer emulator is based on the following global mean equations:

$$C\frac{\mathrm{d}}{\mathrm{d}t}\Delta T = \Delta F(t) + \alpha\Delta T - \varepsilon\gamma(\Delta T - \Delta T_d)$$
$$C_\mathrm{d}\frac{\mathrm{d}}{\mathrm{d}t}\Delta T_\mathrm{d} = \gamma(\Delta T - \Delta T_d) \qquad \textit{Equation 7.SM.2.1}$$

where ΔT (°C) is the temperature of the surface layer (representing the surface components of the climate system), ΔT_d (°C) is the temperature change in the deep ocean layer, C and C_d are the effective heat capacities for the surface and deep layers in W yr m^{-2} °C^{-1}, ε is the efficacy of the deep ocean heat uptake and γ is the heat transfer coefficient between the surface and deep layer (W m^{-2} °C^{-1}).

The analytical solution of Eq. (7.SM.2.1) is expressed by a combination of fast and slow modes with the decay time scales of τ_f and τ_s. For a given value of ECS, TCR is obtained as

$$\mathrm{TCR} = \mathrm{ECS}\left\{1 - \frac{1}{t}\left[\tau_f a_f\left(1 - e^{-\frac{t_0}{\tau_f}}\right) - \tau_s a_s\left(1 - e^{-\frac{t_0}{\tau_s}}\right)\right]\right\}. \qquad \textit{Equation 7.SM.2.2}$$

The TCR is equal to ΔT at year $t = t_0 = 70$ in response to the forcing ΔF increasing at a rate of 1% per year, and all parameters (τ_f, τ_s, a_f, and a_s) can be calculated using C, C_d, γ, ε and the net feedback parameter α (the formulae are presented in Geoffroy et al. (2013a)). As discussed in Jiménez-de-la-Cuesta and Mauritsen (2019), TCR can also be estimated directly from the two-layer model parameters as $\mathrm{TCR} = \Delta F_{2\times\mathrm{CO2}}/(-\alpha + \kappa)$, where $\kappa = \varepsilon\gamma$.

The two-layer model can be calibrated to emulate the climate response of individual CMIP models (Geoffroy et al., 2013b, 2013a) using *abrupt4xCO2* experiments. Calibrations are performed for 44 CMIP6 models resulting in parameter estimates (mean and standard deviation) of C = 8.1 ± 1.0 W yr m^{-2} °C^{-1}, C_d = 110 ± 63 W yr m^{-2} °C^{-1}, γ = 0.62 ± 0.13 W m^{-2} °C^{-1}, ε = 1.34 ± 0.41, κ = 0.84 ± 0.38 W m^{-2} °C^{-1}. Representative values from CMIP6 models in Eq. (7.SM.2.2) are τ_f = 4.6 yr, τ_s = 333 yr, a_f = 0.541, a_s = 0.459.

7.SM.2.2 Constrained emulator ensemble

In several places in Working Group I (Chapter 1, Figure 7.7, Figure 7.8, Chapter 9), a constrained ensemble of two-layer model projections is used. The starting point for this ensemble is a 1 million-member ensemble of emissions-driven historical runs using v1.6.2 of the FaIR emulator (Millar et al., 2017; Smith et al., 2018a). The temperature module of FaIR is mathematically equivalent to the two-layer emulator in Eq. (7.SM.2.1), and the emissions- or concentrations-to-ERF relationships in FaIR are equivalent or very similar to those described in generating the ERF time series in Section 7.SM.1. The similarity of the two-layer model to FaIR is demonstrated in Figure 7.SM.2.

The 1 million ensemble members sample the uncertainty in the ERF, the climate response, and the carbon cycle. ERF uncertainties are generated using the same method described in Section 7.SM.1.3. For the climate response, the C, C_d, γ and ε components of the two-layer model in Eq. 7.SM.2.1 are generated from kernel-

density estimates that are calibrated to 44 CMIP6 models (Section 7.SM.2.1). The climate feedback parameter α is sampled from a truncated Gaussian distribution (truncated at ±2 standard deviations) with mean –1.33 W m^{-2} °C^{-1} and standard deviation 0.5 W m^{-2} °C^{-1}. The carbon cycle in FaIR is parameterised by the pre-industrial time-integrated airborne fraction of CO_2, and the change in airborne fraction with accumulated carbon emissions and GSAT change (Millar et al., 2017). These parameters are sampled as uniform distributions using the lowest and highest values based on calibrations to 11 CMIP6 models (Arora et al., 2020) as the bounds of the distributions. The 1 million-member ensemble was run in the FaIR model using emissions-driven runs from 1750 to 2019. The resulting ensemble was constrained based on agreement to:

(1) the time series of historical GSAT to the Chapter 2 (Cross Chapter Box 2.3) assessment from 1850–2020 with a root-mean-square error of 0.135°C or less, approximately recreating the headline 1850–1900 to 1995–2014 assessment of 0.67–0.98°C (Cross Chapter Box 2.3, *very likely* range);
(2) the assessment of ocean heat uptake from Section 7.2.2.2 from 1971–2018 within the *likely* range of 329–463 ZJ;
(3) CO_2 concentrations to the 2014 *very likely* range of 397.1 ± 0.4 ppm (Table 2.1);
(4) the airborne fraction from a 1% per year CO_2 increase simulation to the range assessed in Section 5.5.1 of 53 ± 6% (1 standard deviation).

From the original 1 million-member ensemble, 2,237 ensemble members passed all four constraints and are used for reporting results. This constrained ensemble set from FaIRv1.6.2 has a good correspondence to assessed ranges of key climate metrics across the Working Group I report (Cross Chapter Box 7.1 Table 1; Table 7.SM.4). While not used as formal constraints, the assessed distributions of ECS and TCR (Section 7.5.2) and projected future warming from the five major SSP scenarios (Section 4.3.4) were used as guidelines to ensure simultaneous adherence to several assessed ranges. As a comparison, the ECS from this constrained set has a median and 5–95% ranges of ECS and TCR of 2.95 [2.05 – 5.07]°C and 1.81 [1.36–2.46]°C respectively, compared to the Chapter 7 best estimates and *very likely* ranges of 3.0 [2.0–5.0]°C for ECS and 1.8 [1.2 – 2.4]°C for TCR. While constraints (3) and (4) are not required when running FaIR or the two-layer model using prescribed historical greenhouse gas concentrations, this 2,237 member ensemble set is intended to be used to evaluate future warming pathways to integrated assessment model scenario projections in Chapter 3 of Working Group III, so the same ensemble set is used here for overall consistency.

7.SM.2.3 Supporting information for Figures 7.7 and 7.8

The data contributing to Figures 7.7 and 7.8 is from the 2,237-member constrained ensemble described in Section 7.SM.2.2. To provide the contributions to historical temperature in Figures 7.7 and 7.8, one of the 13 components of the historical forcing at a time is removed from the total forcing, and the two-layer model run using the forcing and climate configuration from each of the 2,237 ensemble members. The difference between the all-forcing and leave-one-out model run provides the temperature contribution from each forcing agent. This exercise was repeated using a best-estimate climate response (hence, only assessing the impact of uncertainty in the ERF) by setting ECS = 3.0°C, TCR 1.8°C and the other two-layer model parameters set to their CMIP6 model means (C = 8.1 W yr m^{-2} °C^{-1}, C_d = 110 W yr m^{-2} °C^{-1}, γ = 0.64 W m^{-2} °C^{-1} and ε = 1.36; Section 7.SM.2.1). These simulations are shown as dashed error bars in Figure 7.7, with the full ERF and climate response uncertainty as solid error bars.

Each ensemble member uses a long (approximately 9,000-year) pre-industrial spin-up comprising only transient solar and volcanic forcing starting in 6755 BCE (Section 7.SM.1.3), and temperature changes are reported with respect to 1750 as a single baseline year. The same 2,237 ensemble member set was extended forward in time to 2500 under forcing from the SSP scenarios (Section 7.SM.1.4) and used to inform global-mean sea level projections in Chapter 9.

7.SM.3 Performance of emulators compared to key physical climate assessments

Table 7.SM.4 details the performance of the four emulators (CICERO-SCM, FaIRv1.6.2, MAGICC7.5.1 and OSCARv3.1.1) described in Cross Chapter Box 7.1 for a number of climate assessments in absolute terms, and can be compared to Cross Chapter Box 7.1 Table 2 which details the relative difference between each emulator and the AR6 assessed range.

[START TABLE 7.SM.4 HERE]

Table 7.SM.4: Absolute differences between the emulator value and the Working Group I assessed best estimate and range for key climate assessments. Values are given for four emulators in their respective AR6-calibrated probabilistic setups. Relative values of these indicators are shown in Cross Chapter Box 7.1, Table 2. Emulator values within 5% of the assessed central value and 10% of the lower and upper ranges are unshaded, showing good correspondence between the emulator and the assessment. The columns labelled "upper" and "lower" indicate *very likely* (5% to 95%) ranges, except for the variables demarcated with an asterisk or double asterisk (* or **), where they denote *likely* ranges from 17% to 83%. Note that the TCRE assessed range (**) is wider than the combination of the TCR and airborne fraction to account for uncertainties related to model limitations.

The comparison of the constrained two-layer emulator to FaIRv1.6.2 and MAGICC7.5.1 is shown in Figure 7.SM.3 for the SSP1-2.6 and SSP5-8.5 scenarios, demonstrating the similarity between the FaIR and two-layer projections as well as the similarity between FaIR and MAGICC in their AR6 setups.

[START FIGURE 7.SM.2 HERE]

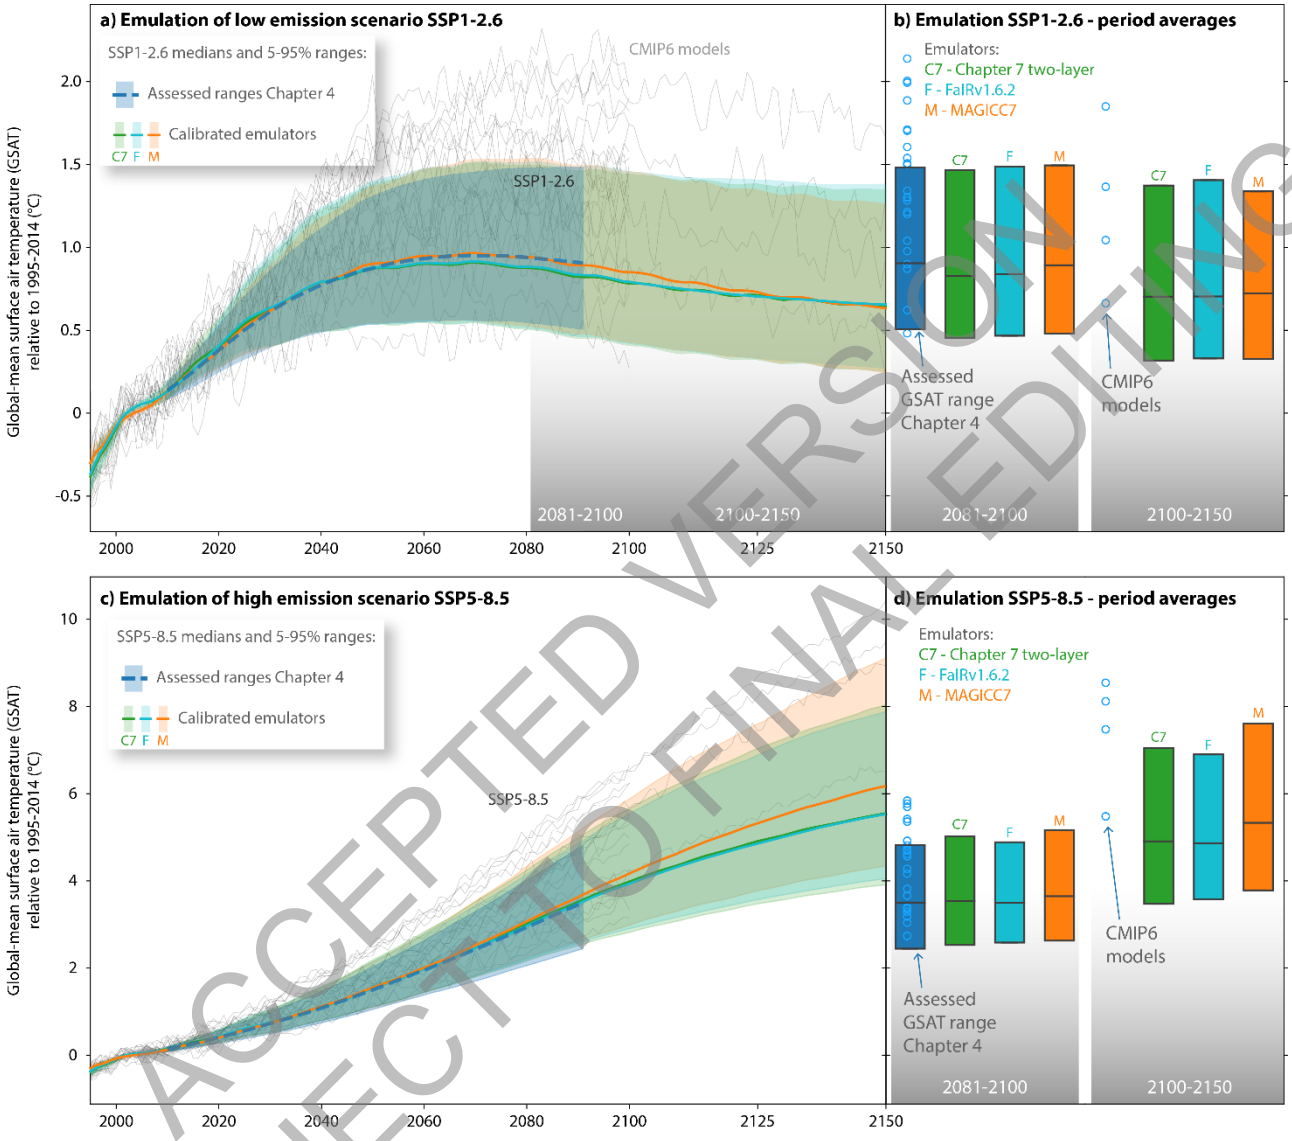

Figure 7.SM.2: (a) Time series and (b) 2100-2150 means of emulated GSAT projections from the Chapter 7 two-layer model (green), FAIRv1.6.2 (light blue), and MAGICC7.5.1 (orange) from 1995 to 2150, following the SSP1-2.6 scenario ((a) and (b)) and the SSP5-8.5 scenario ((c) and (d)). In (a) and (c) the ensemble median estimates are solid lines and the 5–95% ranges are shaded; in (b) and (d) the bar range shows 5–95% ranges with the median in black. Overlaid CMIP6 model results are shown as lines in (a) and (c), and dots in (b) and (d) (fewer dots are shown for the 2100–2150 period because only a limited number of CMIP6 models have performed runs beyond 2100). In (a) and (c), Chapter 4 assessed GSAT projections (20-year running means) are shown with a dark blue dashed line and 5-95% range in dark blue shading.

7.SM.4 Equilibrium Climate Sensitivity and Transient Climate Response from CMIP6 models

Table 7.SM.5 details the equilibrium climate sensitivity and transient climate response estimated from CMIP6 and CMIP5 models using the ESMValTool (Eyring et al., 2020; Lauer et al., 2020; Righi et al., 2020) and presented in Schlund et al. (2020) for ECS and Meehl et al. (2020) for TCR (CMIP6 only), used in Section 7.5.6, Figure 7.18 and FAQ 7.3. Climate feedback parameters, including the decomposition into Planck, water vapour plus lapse rate, surface albedo and cloud components, plus the residual, are given for CMIP6 and CMIP5 models from Zelinka et al. (2020). ECS is estimated from a 150-year integration of an *abrupt4xCO2* experiment, subtracting the parallel *piControl* integration from the same period, regressing the modelled top-of-atmosphere energy imbalance ΔN against the modelled GSAT change ΔT, and taking $\Delta T/2$ at the point where the regression slope crosses $\Delta N = 0$ (Gregory et al., 2004). TCR is estimated from the mean ΔT change from a *1pctCO2* run compared to the parallel *piControl* integration in years 60 to 79. Feedback contributions are estimated from a mean of six radiative kernels presented in Zelinka et al. (2020).

[START TABLE 7.SM.5 HERE]

Table 7.SM.5: Equilibrium climate sensitivity (ECS) and climate feedbacks estimated from CMIP5 and CMIP6 models. Transient climate response (TCR) from CMIP6 models is also provided. Data from Schlund et al. (2020), Meehl et al. (2020) and Zelinka et al. (2020).

7.SM.5 Climate metrics

7.SM.5.1 Definitions of climate metrics

Absolute Global Forcing Potential:

$$A\mathrm{GFP}_X(H) = \Delta F_X(H) \qquad \textit{Equation 7.SM.5.1}$$

Absolute Global Warming Potential

$$A\mathrm{GWP}_X(H) = \int_0^H \Delta F_X(t)dt \qquad \textit{Equation 7.SM.5.2}$$

Absolute Global Temperature-change Potential:

$$A\mathrm{GTP}^X(H) = \Delta T^X(H) = \int_0^H A\mathrm{GFP}^X(t)R_\mathrm{T}(H-t)dt \qquad \textit{Equation 7.SM.5.3}$$

Absolute Global Sea-level Rise:

$$A\mathrm{GSR}^X(H) = \Delta\mathrm{SLR}^X(H) = \int_0^H A\mathrm{GTP}^X(t)R_\mathrm{SLR}(H-t)dt$$
$$= \int_0^H \int_0^t \mathrm{AGFP}^X(t')R_\mathrm{T}(t-t')R_\mathrm{SLR}(H-t)dt'dt$$

Equation 7.SM.5.4

where R_SLR is the sea-level rise resulting from a pulse temperature increase (Sterner et al., 2014).

Increase in absolute metric ($\Delta\mathrm{AGxx}^X$) due to the carbon cycle response:

$$\Delta\mathrm{AGxx}^X = \int_0^H \int_0^t AGTP^X(t')\gamma r_F(t-t')\mathrm{AGxx}^{\mathrm{CO2}}(H-t)dt'dt \qquad \textit{Equation 7.SM.5.5}$$

where $\gamma r_F(t)$ is the CO_2 flux perturbation following a unit temperature pulse in $kgCO_2\ yr^{-1}\ K^{-1}$ using the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

parameterisation of Gasser et al. (2017b), and

$$r_F = \delta(t) - \frac{\alpha_1}{\tau_1} e^{-\frac{t}{\tau_1}} - \frac{\alpha_2}{\tau_2} e^{-\frac{t}{\tau_2}} - \frac{\alpha_3}{\tau_3} e^{-\frac{t}{\tau_3}} \qquad \textit{Equation 7.SM.5.6}$$

and the parameters used in Eqs. (7.SM.4.5) and (7.SM.4.6) are given in Table 7.SM.6.

[START TABLE 7.SM.6 HERE]

Table 7.SM.6: Parameters for the carbon cycle response function (from table 1 of (Gasser et al., 2017b)).

γ ($kgCO_2\ yr^{-1}\ °C^{-1}$)	α_1	α_2	α_3	τ_1 (yr)	τ_2 (yr)	τ_3 (yr)
11.06×10^{12}	0.6368	0.3322	0.00310	2.376	30.14	490.1

[END TABLE 7.SM.6 HERE]

Metrics for step emission changes can be derived by integrating the more standard pulse emission changes up to the time horizon:

$$\mathrm{AGTP}_X^S = \int_0^H \mathrm{AGTP}_X(H-t)dt \qquad \textit{Equation 7.SM.5.7}$$

The contribution to methane emission metrics from CO_2 from methane oxidation is given by

$$\Delta\mathrm{AGxx}^X = \int_0^H Y \frac{m_{\mathrm{CO_2}}}{m_{\mathrm{CH_4}}} \frac{1}{\tau_{\mathrm{OH}}} e^{-\frac{(H-t)}{\tau_{\mathrm{OH}}}} \mathrm{AGxx}^{\mathrm{CO2}}(H-t)dt \qquad \textit{Equation 7.SM.5.8}$$

where Y is the fractional molar yield of CO_2 from CH_4 oxidation (see Section 7.6.1.3), $m_{\mathrm{CO_2}}$ and $m_{\mathrm{CH_4}}$ are the molar masses of CO_2 and CH_4, and τ_{OH} is the methane oxidation lifetime time to OH (9.7 yr; Section 6.3.1).

7.SM.5.2 Impulse response functions for GTP and Chapter 6 calculations

To generate a suite of two-layer configurations for uncertainty estimates in GTP calculations (Tables 7.SM.8–7.SM.13), information from the FaIRv1.6.2 and MAGICC7.5.1 AR6 calibration setups (Cross Chapter Box 7.1) are used. FaIRv1.6.2 uses the two-layer model in Eq. (7.SM.2.1) as its core so converting its parameters to two-layer configurations is trivial (discussed in Section 7.SM.2.2). To convert MAGICC7.5.1's configuration to two-layer configurations, the two-layer model parameters are fitted to MAGICC7.5.1's output from an abrupt $2\times CO_2$ experiment. However, such a fitting procedure produces only an approximate translation because MAGICC7.5.1 is not well-represented by a two-timescale model. After these two conversions are done an ensemble of two-layer configurations is generated which is used for uncertainty analysis in GTP calculations.

To generate the Chapter 6 two-layer configuration, the timescales and efficacy parameters are calculated as the average of FaIRv1.6.2's median and a fit to MAGICC7.5.1's median response (both in their AR6 calibrations). Response magnitudes that describe the contributions to the fast and slow response timescales are calculated such that the Chapter 6 configuration matches the best-estimate ECS of 3.0°C and TCR of 1.8°C (Table 7.13) under the best-estimate ERF due to a doubling of CO_2 of 3.93 W m^{-2}. This results in parameter values for C = 7.7 W yr m^{-2} $°C^{-1}$, C_d = 147 W yr m^{-2} $°C^{-1}$, α = –1.31 W m^{-2} $°C^{-1}$, ε = 1.03, κ =

ACCEPTED VERSION SUBJECT TO FINAL EDITING

0.88 W m^{-2} °C^{-1}. Note these parameters differ from CMIP6 two-layer model calibrations in Section 7.SM.2.1, as the set described here is derived from a constrained ensemble from two emulators.

7.SM.6 Tables of greenhouse gas lifetimes, radiative efficiencies and metrics

[START TABLE 7.SM.7 HERE]

Table 7.SM.7: Greenhouse gas lifetimes, radiative efficiencies, Global Warming Potentials (GWPs), Global Temperature Potentials (GTPs) and Cumulative Global Temperature Potentials (CGTPs). GWPs given for 20-year, 100-year and 500-year time horizons. GTPs and CGTPs given for 50-year and 100-year time horizons. Note CGTP has units of years and is applied to a change in emission rate rather than a change in emission amount. Also shown are absolute values of GWPs and GTPs (AGWPs and AGTPs), in units of picowatt years per square metre per kilogram (1 pW = 10^{-12} W). Radiative efficiencies for CH_4 and N_2O given in this table do not include chemical adjustments (values including chemical adjustments are given in Table 7.15).

Name	Formula	Lifetime (yr)	Radiative efficiency (W m^{-2} ppb^{-1})	AGWP 20 (pW m^{-2} yr kg^{-1})	GWP 20	AGWP 100 (pW m^{-2} yr kg^{-1})	GWP 100	AGWP 500 (pW m^{-2} yr kg^{-1})	GWP 500	AGTP 50 (pW m^{-2} yr kg^{-1})	GTP 50	AGTP 100 (pW m^{-2} yr kg^{-1})	GTP 100	CGTP 50 (yr)	CGTP 100 (yr)

Table 7.SM.8: Estimated uncertainty in the GWP and GTP for CH_4 showing the total uncertainty as a percentage of the best estimate (expressed as 5-95% confidence interval), and the uncertainty by component of the total emission metric calculation (radiative efficiency, chemistry feedbacks, atmospheric lifetime, CO_2 (combined uncertainty in radiative efficiency and CO_2 impulse response), carbon cycle response, fate of oxidized fossil methane, and impulse-response function. Uncertainties in individual terms are taken from Section 7.6, except for the CO_2 impulse response which comes from (Joos et al., 2013). The impulse-response uncertainties are calculated by taking 1.645×standard deviation of the GTPs generated from 600 ensemble members of the impulse response derived from FaIRv1.6.2 and MAGICC7.5.1 (Section 7.SM.4.2)

Metric	Percentage uncertainty in the metric best estimate due to							Total uncertainty (%)
	Radiative efficiency (%)	Chemical response (%)	Lifetime (%)	CO_2 (%)	Carbon cycle (%)	Fossil fuel oxidation (%)	Impulse Response function (%)

Table Of Contents

Executive Summary **6**

8.1 Introduction **10**

8.1.1 Scope and overview 10
8.1.1.1 Importance of water for human societies and ecosystems 10
8.1.1.2 Overview of the global water cycle in the climate system 11
8.1.2 Summary of water cycle changes from AR5 and special reports 12
8.1.2.1 Summary of observed and projected water cycle changes from AR5 12
8.1.2.2 Key findings of AR6 special reports 13
8.1.3 Chapter motivations, framing and preview 14

8.2 Why should we expect water cycle changes? **15**

8.2.1 Global water cycle constraints 15
8.2.2 Constraints on the regional water cycle 18
8.2.2.1 Thermodynamic constraints on atmospheric moisture fluxes 18
8.2.2.2 Large-scale responses in atmospheric circulation patterns 20
8.2.3 Local-scale physical processes affecting the water cycle 23
8.2.3.1 Hydrological processes related to ice and snow 23
8.2.3.2 Processes determining heavy precipitation and flooding 24
8.2.3.3 Drivers of aridity and drought 26
8.2.3.4 Direct anthropogenic influence on the regional water cycle 28

BOX 8.1: Role of anthropogenic aerosols in water cycle changes **30**

8.3 How is the water cycle changing and why? **32**

8.3.1 Observed water cycle changes based on multiple datasets 32
8.3.1.1 Global water cycle intensity and P-E over land and oceans 32
8.3.1.2 Water vapour and its transport 33
8.3.1.3 Precipitation amount, frequency and intensity 34
8.3.1.4 Evapotranspiration 37
8.3.1.5 Runoff, streamflow and flooding 38
8.3.1.6 Aridity and drought 40
8.3.1.7 Freshwater reservoirs 43
8.3.1.7.1 Glaciers 43
8.3.1.7.2 Seasonal snow cover 43
8.3.1.7.3 Wetlands and lakes 44

Executive Summary

This chapter assesses multiple lines of evidence to evaluate past, present and future changes in the global water cycle. It complements material in Chapters 2, 3, and 4 on observed and projected changes in the water cycle, and Chapters 10 and 11 on regional climate change and extreme events. The assessment includes the physical basis for water cycle changes, observed changes in the water cycle and attribution of their causes, future projections and related key uncertainties, and the potential for abrupt change. Paleoclimate evidence, observations, reanalyses and global and regional model simulations are considered. The assessment shows widespread, non-uniform human-caused alterations of the water cycle, which have been obscured by a competition between different drivers across the 20th century that will be increasingly dominated by greenhouse gas (GHG) forcing at the global scale.

Physical Basis for Water Cycle Changes

Modifications of Earth's energy budget by anthropogenic radiative forcings drive substantial and widespread changes in the global water cycle. There is *high confidence* that global mean precipitation and evaporation increase with global warming, but the estimated rate is model-dependent (*very likely* range of 1–3% per 1°C). The global increase in precipitation is determined by a robust response to global mean surface air temperature (*very likely* 2–3% per 1°C) that is partly offset by fast atmospheric adjustments to atmospheric heating by GHGs and aerosols. The overall effect of anthropogenic aerosols is to reduce global precipitation and alter large-scale atmospheric circulation patterns through their well-understood surface radiative cooling effect (*high confidence*). Land-use and land-cover changes also drive regional water cycle changes through their influence on surface water and energy budgets (*high confidence*). {8.2.1, 8.2.3.4, 8.2.2.2, Box 8.1}

A warmer climate increases moisture transport into weather systems, which, on average, makes wet seasons and events wetter (*high confidence*). An increase in near-surface atmospheric water holding capacity of about 7% per 1°C of warming explains a similar magnitude of intensification of heavy precipitation events (from sub-daily up to seasonal time scales) that increases the severity of flood hazards when these extremes occur (*high confidence*). The severity of very wet and very dry events increases in a warming climate (*high confidence*), but changes in atmospheric circulation patterns alter where and how often these extremes occur with substantial regional differences and seasonal contrasts. The slowdown of tropical circulation with global warming partly offsets the warming-induced strengthening of precipitation in monsoon regions (*high confidence*). {8.2.2, 8.2.3, 8.3.1.7, 8.4.1, 8.5.1}

Warming over land drives an increase in atmospheric evaporative demand and the severity of droughts (*high confidence*). Greater warming over land than over the ocean alters atmospheric circulation patterns and, on average, reduces continental near-surface relative humidity, which contributes to regional drying (*high confidence*). Increasing atmospheric CO_2 concentrations increase plant growth and water-use efficiency, but there is *low confidence* in how these factors drive regional water cycle changes. {8.2.2, 8.2.3}

Causes of Observed Changes

Human-caused climate change has driven detectable changes in the global water cycle since the mid-20th century (*high confidence*). Global warming has contributed to an overall increase in atmospheric moisture and precipitation intensity (*high confidence*), increased terrestrial evapotranspiration (*medium confidence*), influenced global patterns in aridity (*very likely*), and enhanced contrasts in surface salinity and precipitation minus evaporation patterns over the oceans (*high confidence*). {3.4.2, 3.4.3, 3.5.2, 8.3.1, 9.2.2}

Greenhouse gas forcing has driven increased contrasts in precipitation amounts between wet and dry seasons and weather regimes over tropical land areas (*medium confidence*), with a detectable precipitation increase in the northern high latitudes (*high confidence*). GHG forcing has also contributed to drying in dry summer climates, including the Mediterranean, southwestern Australia, southwestern South America, South Africa, and western North America (*medium to high confidence*). Earlier onset of spring snowmelt and increased melting of glaciers have already contributed to seasonal changes in streamflow in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

high-latitude and low-elevation mountain catchments (*high confidence*). {Box 8.2, 8.2.2.1, 8.3.1, 3.3.2, 3.3.3, 3.5.2}

Anthropogenic aerosols have driven detectable large-scale water cycle changes since at least the mid-20th century (*high confidence*). Shifts in the tropical rain belt are associated with the inter-hemispheric temperature response to the time-evolving radiative influence of anthropogenic aerosols and the ongoing warming influence of GHGs (*high confidence*). Cooling in the Northern Hemisphere by sulphate aerosols explained a southward shift in the tropical rain belt and contributed to the Sahel drought from the 1970s to the 1980s (*high confidence*), subsequent recovery from which has been linked with GHG warming (*medium confidence*). Observed changes in regional monsoon precipitation, especially over South Asia, East Asia and West Africa, have been limited over much of the 20th century due to increases driven by warming from GHGs being counteracted by decreases due to cooling from anthropogenic aerosols (*high confidence*). {8.3.1.3, 8.3.2.4, Box 8.1}

Land-use change and water extraction for irrigation have influenced local and regional responses in the water cycle (*high confidence*). Large-scale deforestation has likely decreased evapotranspiration and precipitation and increased runoff over the deforested regions. Urbanization has increased local precipitation (*medium confidence*) and runoff intensity (*high confidence*). Increased precipitation intensities have enhanced groundwater recharge, most notably in tropical regions (*medium confidence*). There is *high confidence* that groundwater depletion has occurred since at least the start of the 21st century as a consequence of groundwater withdrawals for irrigation in agricultural areas in drylands (e.g., the United States southern High Plains, California Central Valley, North China Plain, and northwest India). {8.2.3.4, 8.3.1.7, Box 10.3, FAQ8.1}

Southern Hemisphere storm tracks and associated precipitation have shifted polewards since the 1970s, especially in the austral summer and autumn (*high confidence*). It is *very likely* that these changes are associated with a positive trend in the Southern Annular Mode, related to both stratospheric ozone depletion and GHG increases. There is *medium confidence* that the recent observed expansion of the Hadley Circulation was caused by GHG forcing, especially in the Southern Hemisphere, but there is only *low confidence* in how it influences the drying of subtropical land areas. {8.2.2, 8.3.2, 3.3.3}

Future Water Cycle Changes

Without large-scale reduction in greenhouse gas emissions, global warming is projected to cause substantial changes in the water cycle at both global and regional scales (*high confidence*). Global annual precipitation over land is projected to increase on average by 2.4 [–0.2 to 4.7] % (*very likely* range) in the SSP1-1.9 low-emission scenario and by 8.3 [0.9 to 12.9] % in the SSP5-8.5 high-emission scenario by 2081–2100, relative to 1995–2014. It is *virtually certain* that evaporation will increase over the oceans and *very likely* that evapotranspiration will increase over land with regional exceptions in drying areas. There is *low confidence* in the sign and magnitude of projected changes in global land runoff in all Shared-socioeconomic Pathway scenarios. Projected increases in precipitation amount and intensity will be associated with increased runoff in the northern high latitudes (*high confidence*). There is *high confidence* that mountain glaciers will diminish in all regions and that seasonal snow cover duration will generally decrease. Runoff from small glaciers will typically decrease through loss of ice mass, while runoff from large glaciers is *likely* to increase with increasing global warming until glacier mass becomes depleted (*high confidence*). {4.5.1, 8.4.1}

Increased evapotranspiration due to growing atmospheric water demand will decrease soil moisture over the Mediterranean, southwestern North America, south Africa, southwestern South America, and southwestern Australia (*high confidence*). The total land area subject to increasing drought frequency and severity will expand (*high confidence*), and in the Mediterranean, southwestern South America, and western North America, future aridification will far exceed the magnitude of change seen in the last millennium (*high confidence*). Some tropical regions are also projected to experience increased aridity, including the Amazon basin and Central America (*high confidence*). {8.4.1}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Water cycle variability and extremes are projected to increase faster than average changes in most regions of the world and under all emission scenarios (*high confidence*). In the tropics and in the extratropics of both hemispheres during summer/warm season, interannual variability of precipitation and runoff over land is projected to increase at a faster rate than changes in seasonal mean precipitation amount (*medium confidence*). It is *very likely* that rainfall variability related to the El Niño–Southern Oscillation will be amplified by the end of the 21st century. Sub-seasonal precipitation variability is also projected to increase, with fewer rainy days but increased daily mean precipitation intensity over many land regions (*high confidence*). Precipitation extremes will increase in almost all regions (*high confidence*), even where seasonal mean precipitation is projected to decrease (*medium confidence*). There is *high confidence* that heavy precipitation events associated with both tropical and extratropical cyclones will intensify. {4.5.1.4, 4.5.3.2, 8.2.3.2, 8.4.1, 8.4.2, 8.5.2, 11.7.1.5}

There are contrasting projections in monsoon precipitation, with increases in more regions than decreases (*medium confidence*). Summer monsoon precipitation is projected to increase for the South, Southeast and East Asian monsoon domains, while North American monsoon precipitation is projected to decrease (*medium confidence*). West African monsoon precipitation is projected to increase over the Central Sahel and decrease over the far western Sahel (*medium confidence*). There is *low confidence* in projected precipitation changes in the South American and Australian monsoons (for both magnitude and sign). There is *high confidence* that the monsoon season will be delayed in North and South America and *medium confidence* that it will be delayed in the Sahel. {8.2.2, 8.4.2.4}

Precipitation associated with extratropical storms and atmospheric rivers will increase in the future in most regions (*high confidence*). A continued poleward shift of storm tracks in the Southern Hemisphere (*likely*) and the North Pacific (*medium confidence*) will lead to similar shifts in annual or seasonal precipitation. There is *low confidence* in projections of blocking and stationary waves and therefore their influence on precipitation for almost all regions. {8.4.2}

The seasonality of precipitation, water availability and streamflow will increase with global warming over the Amazon (*medium confidence*) and in the subtropics, especially in the Mediterranean and southern Africa (*high confidence*). The annual contrast between the wettest and driest month of the year is *likely* to increase by 3–5% per 1°C in most monsoon regions in terms of precipitation, precipitation minus evaporation, and runoff (*medium confidence*). There is *high confidence* in an earlier onset in spring snowmelt, with higher peak flows at the expense of summer flows in snow-dominated regions globally, but *medium confidence* that reduced snow volume in lower-latitude regions will reduce runoff from snowmelt. {8.2.2, Box 8.2, 8.4.1.7, 8.4.2.4}

Confidence in Projections, Non-Linear Responses and the Potential for Abrupt Changes

Representation of key physical processes has improved in global climate models (GCMs), but they are still limited in their ability to simulate all aspects of the present-day water cycle and to agree on future changes (*high confidence*). Climate change studies benefit from sampling the full distribution of model outputs when considering future projections at regional scales. Increasing horizontal resolution in GCMs improves the representation of small-scale features and the statistics of daily precipitation (*high confidence*). High-resolution climate and hydrological models provide a better representation of land surfaces, including topography, vegetation and land-use change, which improve the accuracy of simulations of regional changes in the water cycle (*high confidence*). There is *high confidence* in the potential added value of regional climate models but only *medium confidence* that this potential is currently realized. {8.5.1}

Natural climate variability will continue to be a major source of uncertainty in near-term (2021–2040) water cycle projections (*high confidence*). Decadal predictions of water cycle changes should be considered with *low confidence* in most land areas because the internal variability of precipitation is difficult to predict and can offset or amplify the forced water cycle response. Water cycle changes that have already emerged from natural variability will become more pronounced in the near term, but the occurrence of volcanic eruptions (either single large events or clustered smaller ones) can alter the water cycle for several years, decreasing global mean land precipitation and altering monsoon circulation (*high confidence*). {8.5.2,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

CCB4.1}

Continued global warming will further amplify GHG-induced changes in large-scale atmospheric circulation and precipitation patterns (*high confidence*), but in some cases regional water cycle changes are not linearly related to global warming. Non-linear water cycle responses are explained by the interaction of multiple drivers, feedbacks and time scales (*high confidence*). Nonlinear responses of regional runoff, groundwater recharge and water scarcity highlight the limitations of simple pattern-scaling techniques (*medium confidence*). Water resources fed by melting glaciers are particularly exposed to nonlinear responses (*high confidence*). {8.5.3}

Abrupt human-caused changes to the water cycle cannot be excluded. There is evidence of abrupt change in some high-emission scenarios, but there is no overall consistency regarding the magnitude and timing of such changes. Positive land-surface feedbacks, including vegetation and dust, can contribute to abrupt changes in aridity, but there is only *low confidence* that such changes will occur during the 21st century. Continued Amazon deforestation, combined with a warming climate, raises the probability that this ecosystem will cross a tipping point into a dry state during the 21st century (*low confidence*). The paleoclimate record shows that a collapse in the Atlantic Meridional Overturning Circulation (AMOC) causes abrupt shifts in the water cycle (*high confidence*), such as a southward shift in the tropical rain belt, weakening of the African and Asian monsoons and strengthening of Southern Hemisphere monsoons. There is *medium confidence* that AMOC will not collapse before 2100, but should it collapse, it is *very likely* that there would be abrupt changes in the water cycle. {8.6.1, 8.6.2}

Solar radiation modification (SRM) could drive abrupt changes in the water cycle (*high confidence*). It is *very likely* that abrupt water cycle changes will occur if SRM techniques are implemented rapidly or terminated abruptly. The impact of SRM is spatially heterogeneous (*high confidence*), will not fully mitigate the GHG-forced water cycle changes (*medium confidence*), and can affect different regions in potentially disruptive ways (*low confidence*). {8.6.3}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

8.1 Introduction

8.1.1 Scope and overview

8.1.1.1 Importance of water for human societies and ecosystems

Water is vital to all life on Earth. 71% of the Earth is covered by water, with saline ocean water accounting for around 96.6% of total water availability (Figure 8.1). Terrestrial freshwater only represents about 1.8% of all water on Earth and the remainder (1.6%) is primarily made up of saline groundwater and saline lakes (Durack, 2015; Abbott et al., 2019). Ice sheets, glaciers and snow pack account for approximately 97% of freshwater resources, with less than 3% of freshwater considered easily accessible and available for essential ecosystem functioning and human society's water resource needs (Durack, 2015; Abbott et al., 2019). This very small fraction of freshwater represents a total volume of about 835 thousand km^3, mostly contained in groundwater (630 thousand km^3), the remaining 205 thousand km^3 being stored in lakes, rivers, wetlands and soils (Abbott et al., 2019). Although the natural cycling rate of this amount is theoretically enough to meet global human and ecosystem needs, there are large geographical and seasonal differences that influence the availability of freshwater to meet regional demands.

Freshwater is the most essential natural resource on the planet (Mekonnen and Hoekstra, 2016; Djehdian et al., 2019) and underpins almost all Sustainable Development Goals (SDGs), which require access to adequate and safe resources for drinking and sanitation (SDG 6) and many other purposes. Freshwater supports a range of human activities from irrigation to industrial processes including the generation of hydroelectricity and the cooling of thermoelectric power plants (Bates et al., 2008; Schewe et al., 2014). These activities require sufficient quantities of freshwater that can be drawn from rivers, lakes, groundwater stores, and in some cases, desalinated sea water (Schewe et al., 2014). Recent estimates of global water pools and fluxes suggest that half of global river discharge is redistributed each year by human water use (Abbott et al., 2019). This emphasises the need to consider both anthropogenic climate change and direct human influences, such as population increase or migration, economic development, urbanization, and land use change, when planning water-related mitigation or adaptation strategies (Jiménez Cisneros et al., 2014).

Water scarcity occurs when there are insufficient freshwater resources to meet water demands, although water problems may also arise from water quality issues or from economic and institutional barriers (WGII Chapter 4). This affects the preservation of environmental flows that ultimately influence ecosystem functioning and services (Schewe et al., 2014; Mekonnen and Hoekstra, 2016; Djehdian et al., 2019). As such, water availability is a major constraint on human society's ability to meet the future food and energy needs of a growing population (D'Odorico et al., 2018). Water plays a key role in the production of energy, including hydroelectricity, bioenergy, and the extraction of unconventional fossil fuels (Schewe et al., 2014; D'Odorico et al., 2018; Djehdian et al., 2019). These dependencies have resulted in increasing competition for water between the food and energy sectors. Pressures on this 'food-energy-water nexus' are further compounded by increasing globalization, which can transfer large-scale water demands to other regions of the world, raising serious concerns about local food and water security in regions that are highly dependent on agricultural exports or imports (D'Odorico et al., 2018).

The consequences of climate change on terrestrial ecosystems and human societies are primarily experienced through changes to the global water cycle (Jiménez Cisneros et al., 2014). Changes in the quantity and seasonality of water due to climate change have long been recognized by IPCC and global development agencies as heavily influencing the food security and economic prosperity of many countries, particularly in the arid and semi-arid areas of the world including Asia, Africa, Australia, Latin America, the Mediterranean, and small island developing states (Bates et al., 2008; Schewe et al., 2014; Mekonnen and Hoekstra, 2016). Having too much or too little water increases the likelihood of flooding and drought, as precipitation variability increases in a warming climate (Stocker et al., 2013; Hoegh-Guldberg et al., 2019). Climate change poses a threat to both regional water availability and global water security. Changes in precipitation and glacier runoff and snowmelt influence other hydroclimate variables like surface and subsurface runoff, and groundwater recharge, which are critical to the water, food and energy security of many regions (Oki and Kanae, 2006; Jiménez Cisneros et al., 2014; Schewe et al., 2014; Mekonnen and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Hoekstra, 2016).

Currently, around four billion people live under conditions of severe freshwater scarcity for at least one month of the year, with half a billion people in the world facing severe water scarcity all year round (Mekonnen and Hoekstra, 2016). AR5 WGII reported that approximately 80% of the world's population already suffers from high levels of threat to water security (Jiménez Cisneros et al., 2014). Given the vulnerability of the planet's freshwater resources and the role of climate change in intensifying adverse impacts on human societies and ecosystems (IPCC, 2018; Hoegh-Guldberg et al., 2019), this chapter evaluates advances in the theoretical, observational and model based understanding of the global water cycle made since AR5 (IPCC, 2013) and AR6 Special Reports.

8.1.1.2 Overview of the global water cycle in the climate system

As shown in Figure 8.1, the global water cycle is the continuous, naturally occurring movement of water through the climate system from its liquid, solid and gaseous forms among reservoirs of the ocean, atmosphere, cryosphere and land (Stocker et al., 2013). In the atmosphere, water primarily occurs as a gas (water vapour), but it is also present as ice and liquid water within clouds where it substantially affects Earth's energy balance (Section 7.4.2.2 and 7.4.2.4). The water cycle primarily involves the evaporation[1] and precipitation of moisture at the Earth's surface including transpiration associated with biological processes. Water that falls on land as precipitation, supplying soil moisture, groundwater recharge, and river flows, was once evaporated from the ocean or sublimated from ice-covered regions before being transported through the atmosphere as water vapour, or in some areas was generated over land through evapotranspiration (Gimeno et al., 2010; van der Ent and Savenije, 2013). In addition, the net flux of atmospheric and continental freshwater is a key driver of sea surface salinity, which in turn influences the density and circulation of the ocean (Chapter 9).

Understanding the interactions between the water and energy cycles is one of the four core projects of the World Climate Research Programme (WCRP). Latent heat fluxes, released by condensation of atmospheric water vapour and absorbed by evaporative processes, are critical to driving the circulation of the atmosphere on scales ranging from individual thunderstorm cells to the global circulation of the atmosphere (Stocker et al., 2013; Miralles et al., 2019). Water vapour is the most important gaseous absorber in the Earth's atmosphere, playing a key role in the Earth's radiative budget (Schneider et al., 2010). As atmospheric water vapour content increases with temperature, it has a considerable influence on climate change (Section 7.4.2.2). Additionally, a small fraction of the atmospheric water content is liquid or solid and has a major effect on both solar and longwave radiative fluxes, from the Earth's surface to the top of the atmosphere. The cloud response to anthropogenic radiative forcings, both in the tropics and in the extratropics (Zelinka et al., 2020), is therefore also crucial for understanding climate change (Section 7.4.2.4).

The terrestrial water and carbon cycles are also strongly coupled (Cross-Chapter Box5.1). As atmospheric carbon dioxide (CO_2) concentration increases, the physical environment in which plants grow is altered, including the availability of soil moisture necessary for plants' CO_2 uptake and, potentially, the effectiveness of carbon dioxide removal techniques to mitigate climate change (Section 5.6.2.1.2). Rising surface CO_2 concentrations also modify stomatal (small pores at the leaf surface) regulation as well as the plants' biomass, thus affecting ecosystem photosynthesis and transpiration rates and leading generally to a net increase in water use efficiency (Lemordant et al., 2018). These coupled changes have profound implications for the simulation of the carbon and water cycles (Gentine et al., 2019; see also Section 5.4.1), which can be better assessed with the new generation Earth system models, although both the carbon concentration and carbon-climate feedbacks remain highly uncertain over land (Arora et al., 2020) {5.4.5}. The water constraints on the terrestrial carbon sinks are a matter of debate regarding the feasibility or efficiency of

[1] In this chapter, we use evaporation to include all evaporative processes that include transpiration over land while the term evapotranspiration (ET) is also used interchangeably when the focus is only on land.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

some land-based carbon dioxide removal and sequestration techniques requested to comply with the Paris Agreement (Fuss et al., 2018; Belyazid and Giuliana, 2019) {5.6.2.2.1}.

[START FIGURE 8.1 HERE]

Figure 8.1: Depiction of the water cycle based on previous assessments (Trenberth et al., 2011; Rodell et al., 2015; Abbott et al., 2019) with minor adjustments for groundwater flows (Kwon et al., 2014; Zhou et al., 2019c; Luijendijk et al., 2020), seasonal snow (Pulliainen et al., 2020) and ocean precipitation and evaporation (Stephens et al., 2012; Allan et al., 2020; Gutenstein et al., 2020). In the atmosphere, which accounts for only 0.001% of all water on Earth, water primarily occurs as a gas (water vapour), but it is also present as ice and liquid water within clouds. The ocean is the primary water reservoir on Earth, which is comprised mostly of liquid water across much of the globe, but also includes areas covered by ice in polar regions. Liquid freshwater on land forms surface water (lakes, rivers), soil moisture and groundwater stores, together accounting for 1.8% of global water (Stocker et al., 2013). Solid terrestrial water that occurs as ice sheets, glaciers, snow and ice on the surface and permafrost currently represents 2.2% of the planet's water (Stocker et al., 2013). Water that falls as snow in winter provides soil moisture and streamflow after melting, which are essential for human activities and ecosystem functioning.

[END FIGURE 8.1 HERE]

8.1.2 Summary of water cycle changes from AR5 and special reports

This Report is the first IPCC assessment to include a chapter specifically dedicated to providing an integrated assessment of the global water cycle changes, by building on many chapters from previous reports. This section summarises observed and projected water cycle changes reported in the AR5 (IPCC, 2013) and in the recent IPCC special reports on global warming of 1.5ºC (SR1.5), ocean and cryosphere in a changing climate (SROCC), and climate change and land (SRCCL).

8.1.2.1 Summary of observed and projected water cycle changes from AR5

Based on long-term observational evidence (Hartmann et al., 2013), AR5 concluded it was *likely* that anthropogenic influence has affected the water cycle since the 1960s (IPCC, 2018). Detectable human influence on changes to the water cycle were found in atmospheric moisture content (*medium confidence*), global-scale changes of precipitation over land (*medium confidence*), intensification of heavy precipitation events over land regions where sufficient data networks exist (*medium confidence*), and *very likely* changes to ocean salinity through its connection with evaporation minus precipitation change patterns (Stocker et al., 2013) {2.5, 2.6, 3.3, 7.6, 10.3, 10.4}. AR5 also reported that it is *very likely* that global surface air specific humidity increased since the 1970s. There was *low confidence* in the observations of global-scale cloud variability and trends, *medium confidence* in reductions of pan-evaporation, and *medium confidence* in the non-monotonic changes of global evapotranspiration since the 1980s. In terms of streamflow and runoff, the AR5 identified that there is *low confidence* in the observed increasing trends of global river discharge during the 20th century. Similarly, AR5 concluded that there is *low confidence* in any global-scale observed trend in drought or dryness (lack of rainfall) since the mid-20th century. Yet, the frequency and intensity of drought *likely* increased in the Mediterranean and West Africa, while they *likely* decreased in central North America and north-western Australia since 1950.

Water cycle projections in AR5 (Collins et al., 2013) were considered primarily in terms of water vapour, precipitation, surface evaporation, runoff, and snowpack. Globally-averaged precipitation was projected to increase with global warming with *virtual certainty* (12ES, 12.4.1.1). Regionally, precipitation in some areas of the tropics and polar regions could increase by more than 50% by the end of the 21st century under the RCP8.5 emissions scenario, while precipitation in large areas of the subtropics could decrease by 30% or more (AR5 FAQ 12.2, Figure 12.22). Overall, the contrast of annual mean precipitation between dry and wet regions and between dry and wet seasons ("wet-get-wetter and dry-get-drier") was projected to increase over

ACCEPTED VERSION SUBJECT TO FINAL EDITING

most of the globe with *high confidence* (12ES, 12.4.5.2). Globally, the frequency of intense precipitation events was projected to increase while the frequency of all precipitation events was projected to decrease, leading to the contradictory-seeming projection of a simultaneous increase in both droughts and floods (AR5 FAQ 12.2, 12.4.5.5). Surface evaporation change was projected to be positive over most of the ocean and to generally follow the pattern of precipitation change over land (12ES, 12.4.5.4). Near-surface relative humidity reductions over many land areas were projected to be *likely*, with *medium confidence* (12.4.5.1). General decreases in soil moisture in present-day dry regions were considered *likely,* and projected with *medium confidence* under the RCP8.5 scenario (12.4.5.3). Soil moisture drying in the Mediterranean, southwest USA and southern African regions was considered *likely*, with *high confidence* by the end of this century under the RCP8.5 scenario (12.4.5.3). Projections for annual runoff included both decreases and increases. Decreases in Northern Hemisphere snow cover were assessed as *very likely* with continued global warming (12.4.6.2). As temperatures increase, snow accumulation was projected to begin later in the year and melting to start earlier, with related changes in snowmelt-driven river flows (AR5 FAQ 12.2, 12.4.6.2). In terms of the potential for abrupt change in components of the water cycle, long-term droughts and monsoonal circulation were identified as potentially undergoing rapid changes, but the assessment was reported with *low confidence* (Table 12.4, 12.5.5.8.1, 12.5.5.8.2).

8.1.2.2 Key findings of AR6 special reports

The SR1.5 assessed the impacts of global warming of 1.5°C above pre-industrial levels. The dominant human influence on observed global warming and related water cycle changes was confirmed. Further evidence that anthropogenic global warming has caused an increase in the frequency, intensity and/or amount of heavy precipitation events at the global scale (*medium confidence*), as well as in drought occurrence in the Mediterranean region (*medium confidence*) was also reported. Chapter 3 of SR1.5 (Hoegh-Guldberg et al., 2019) highlights that each half degree of additional global warming influences the climate response. Heavy precipitation shows a global tendency to increase more at 2°C compared to 1.5°C, though there is *low confidence* in projected regional differences in heavy precipitation at 1.5°C compared to 2°C global warming, except at high latitudes or at high altitude where there is *medium confidence*. A key finding is that "limiting global warming to 1.5°C compared to 2°C would approximately halve the proportion of the world population expected to suffer water scarcity, although there is considerable variability between regions (*medium confidence*)" (SR1.5). This is consistent with greater adverse impacts found at 2°C compared to 1.5°C for a number of dryness or drought indices (Schleussner et al., 2016; Lehner et al., 2017; Greve et al., 2018). There is also *medium confidence* that land areas with increased runoff and exposure to flood hazards will increase more at 2°C compared to 1.5°C of global warming.

The Special Report on the Ocean and Cryosphere in a changing Climate (SROCC) provides a comprehensive assessment of recent and projected changes, specifically in snow and ice-covered areas that form a key component of the water cycle in high-elevation and high-latitudes areas. High mountain regions have experienced significant warming since the early 20th century, resulting in reduced snowpack on average (Marty et al., 2017), with glaciers retreating globally since the mid-20th century (Marzeion 2018; Zemp et al., 2019). Glacier shrinkage and snow cover changes have led to changes (both increases and decreases) in streamflow in many mountain regions in recent decades (Milner et al., 2017). Permafrost regions have undergone degradation and ground-ice loss due to recent warming (Lu et al., 2017). Glacier mass loss is projected to continue through the 21st century under all scenarios. In high mountain areas, low-elevation snow cover is also projected to decrease, regardless of emissions scenario. Widespread permafrost thaw is projected to continue through this century and beyond. River runoff in snow- or glacier-fed basins is projected to increase in winter and to decrease in summer (and in the annual mean) by 2100. In the oceans, the Atlantic Meridional Overturning Circulation (AMOC) will *very likely* weaken over the 21st century under all emissions scenarios (SROCC), with potential effects on atmospheric circulation and the water cycle at the regional scale (cf. Section 8.6).

The Special Report on climate change, desertification, land degradation, sustainable management, food security, and greenhouse gas fluxes in terrestrial ecosystems (SRCCL) has clear connections with the water cycle. This report indicates that since 1850-1900, land surface temperature has risen nearly twice as much as

ACCEPTED VERSION SUBJECT TO FINAL EDITING

global surface temperature (*high confidence*), with an increase in dry climates (*high confidence*). Land surface processes modulate the likelihood, intensity and duration of many extreme events including droughts (*medium confidence*) and heavy precipitation (*medium confidence*). The direction and magnitude of hydrological changes induced by land use change and land surface feedbacks vary with location and season (*high confidence*). Desertification exacerbates climate change through feedbacks involving vegetation cover, greenhouse gases and mineral dust aerosol (*high confidence*). Urbanisation increases extreme rainfall events over or downwind of cities (*medium confidence*). Intensification of rainy events increase their consequences on land degradation.

8.1.3 Chapter motivations, framing and preview

AR5 report was a major step forward in the assessment of the human influence on the Earth's water cycle, yet regional projections of precipitation and water resources often remained very uncertain for a range of reasons including modelling uncertainty and the large influence of internal variability (Deser et al., 2012; Hawkins and Sutton, 2011; see also Section 1.4.3 and 8.5.2). Since AR5, longer and more homogeneous observational and reanalysis datasets have been produced along with new ensembles of historical simulations driven by all or individual anthropogenic forcings. These factors, together with improved detection-attribution tools, has enabled a more comprehensive assessment and a better understanding of recent observed water cycle changes, including the competing effects of greenhouse gases and aerosol emissions. New paleoclimate reconstructions have been also developed, particularly from the Southern Hemisphere (SH), that were not available at the time of AR5. There have also been advances in modelling clouds, precipitation, surface fluxes, vegetation, snow, floodplains, ground water and other processes relevant to the water cycle. Convection permitting and cloud resolving models have been implemented over increasingly large domains and can be used as benchmarks for the evaluation of the current-generation climate models. The added value of increased resolution in global or regional climate models can be also assessed more thoroughly based on dedicated model intercomparison projects (see Section 10.3.3 and Section 8.5.1). Ongoing research activities on decadal predictions and observational constraints are aimed at narrowing the plausible range of near-term (2021-2040) to long-term (2081-2100) water cycle changes.

This chapter assesses water cycle changes and considers climate change from the perspective of its effects on water availability (including streamflow and soil moisture, snow mass and glaciers, groundwater, wetlands and lakes) rather than only precipitation. The chapter highlights the sensitivity of the water cycle to multiple drivers and the complexity of its responses, depending on regions, seasons and timescales. Anthropogenic drivers include not only emissions of greenhouse gases but also different species of aerosols, land and water management practices. Emphasis is placed on assessing the full range of projections, including 'low likelihood, high impact' climate trajectories such as the potential for abrupt changes in the water cycle.

The chapter starts with theoretical evidence that link small-scale processes and drivers, as well as global energy budget and large-scale circulation constraints to physically-understood changes in the global water cycle (Section 8.2). Observed and projected water cycle changes (Section 8.3 and 8.4, respectively) are assessed in separate sections, but with a parallel structure to facilitate comparison of a specific topic across sections. Projections are primarily assessed on the basis of contrasted emission scenarios to emphasize the water cycle response to mitigation. Unless otherwise specified, projected anomalies are estimated relative to the 1995-2014 baseline climatology and are assessed over 20-year timeslices, 2021-2040, 2041-2060 and 2081-2100 for near-, mid- and long-term changes respectively. Beyond multi-model ensemble means, model response uncertainty, the influence of natural climate variability, and the potential non-linearities in the regional water cycle response are also considered (Section 8.5). Low likelihood but physically plausible high-impact scenarios are also assessed, especially the potential for abrupt climate change (Section 8.6). Final remarks about future studies on water cycle changes (Section 8.7) are also provided, and the chapter addresses three frequently asked questions (FAQs) on the water cycle's sensitivity to land use change (FAQ 8.1), the projected occurrence and severity of floods (FAQ 8.2) and droughts (FAQ 8.3) at the global scale. This chapter outline is summarized with a schematic (Figure 8.2) which also provides a quick guide to the main topics addressed across the different sections.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[START FIGURE 8.2 HERE]

Figure 8.2: Schematic of the chapter structure and quick guide to the chapter content.

[END FIGURE 8.2 HERE]

Chapter 8 has multiple links across all AR6 WGI chapters, so necessarily includes references to other chapter subsections and figures. Model evaluation of large-scale circulation, precipitation, and hydrological extremes is mostly covered by Chapter 3 and 11, respectively, while Chapter 8 focuses on key processes relevant to the water cycle and their resolution-dependent representation in models. Observed and projected changes in large-scale circulation and precipitation are primarily assessed in Chapters 2, 3 and 4. Beyond global and regional mean precipitation amounts, Chapter 8 also focuses on other precipitation properties (e.g., frequency, intensity and seasonality) and other water cycle variables (evapotranspiration, runoff, soil moisture and aridity, solid and liquid freshwater reservoirs). Key regional phenomena (e.g., tropical overturning circulations, monsoons, extratropical stationary waves and stormtracks, modes of variability and related teleconnections) are also assessed given their major dynamical contribution to regional water cycle changes. Although the biosphere and the cryosphere are key components of the water cycle, a more comprehensive assessment of their responses can be found in Chapters 5 and 9, respectively. Further assessment on regional water cycle changes can be found in Chapters 10 to 12 and in the Atlas. The reader is also referred to the interactive Atlas for a more detailed assessment of the range of model biases and responses at the regional scale. Beyond WGI, water is also a major topic for both adaptation and mitigation policies so has strong connections with both WGII and WGIII. Assessment of hydrological impacts at basin and catchment scales, including a broader discussion on adaptation and vulnerability, potential threats to water security, societal responses, improving resilience in water systems and related case studies is provided in WGII (Chapter 4).

8.2 Why should we expect water cycle changes?

It is well understood that global precipitation and evaporation changes are determined by Earth's energy balance (Section 8.2.1). At regional scales smaller than ~4000 km, water cycle changes become dominated by the transport of moisture (Dagan et al., 2019a; Jakob et al., 2019; Dagan and Stier, 2020), which depend on both thermodynamic and dynamical processes (Section 8.2.2). The constraints of energy budgets at global scales and moisture budgets at regional scales cause key water cycle characteristics such as precipitation intensity, duration and intermittence to alter as the climate warms (Pendergrass and Hartmann, 2014b; Döll et al., 2018a). Future water availability is also determined by changes in evaporation, which is driven by a general increase in the atmospheric evaporative demand (Scheff and Frierson, 2014) and modulated by vegetation controls on evaporative losses (Milly and Dunne, 2016; Lemordant et al., 2018; Vicente-Serrano et al., 2020b). At regional scales, water cycle changes result from the interplay between multiple potential drivers (CO_2, aerosols, land use change and human water use; Section 8.2.3). This section assesses advances in physical understanding of global to regional drivers of water cycle changes.

8.2.1 Global water cycle constraints

The Clausius-Clapeyron equation determines that low-altitude specific humidity increases by about 7% per ^{o}C of warming, assuming that relative humidity remains constant, which is approximately true at a global scale but not necessarily valid regionally. It is *very likely* that near surface specific humidity has increased since the 1970s (Section 2.3.1) and total atmospheric water vapour content (precipitable water) is *very likely* to increase at close to a thermodynamic rate on average globally with continued warming. Different radiative forcing mechanisms lead to some variation in the global mean thermodynamic response by altering the relative humidity distribution: the rate of global precipitable water increase with global surface temperature

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ranges[2] from 6.4±1.5% per ºC for sulphate aerosol-induced changes to 9.8±3.3% per ºC for black carbon-induced changes based on idealised modelling (Hodnebrog et al., 2019b). Specific humidity increases at a lower rate over land due to decreasing relative humidity (Collins et al., 2013) as corroborated by observations and simple models (Byrne and O'Gorman, 2018). Prevalent increases in atmospheric water vapour drive powerful amplifying feedbacks (Section 7.4.2.2), intensify atmospheric moisture transport and heavy precipitation events (Section 8.2.3.2), and alter the surface and atmospheric energy balance, thereby influencing global evaporation and precipitation changes (Figure 8.3).

While thermodynamics exert a strong control on water vapour changes, global mean precipitation and evaporation are constrained by the balance of energy fluxes in the atmosphere and at the surface (Figure 8.3). Global mean precipitation increases of 1-3% per ºC of warming, as estimated in AR5 (Collins et al., 2013), are explained as a combination of rapid (or fast) atmospheric adjustments and slow temperature-driven responses (Figure 8.3, panels 1-4) to radiative forcings (Andrews et al., 2010; Bala et al., 2010; Cao et al., 2012). Fast atmospheric adjustments are caused by near-instantaneous (hours to days) changes in the atmospheric energy budget (Figure 8.3, panels 1-3) and atmospheric properties (e.g. temperature, clouds and water vapour) in direct response to the radiative effects of a forcing agent (Sherwood et al., 2015). A further relatively fast (days to months) adjustment of the climate system involves interactions with vegetation and land surface temperature (Figure 8.3, panel 3), which respond more rapidly than ocean temperature to a radiative forcing (Cao et al., 2012; Dong et al., 2014). The slower temperature-dependent precipitation response is driven by the increased atmospheric radiative cooling rate of a warming atmosphere. Warming drives increases in precipitation intensity while frequency is dominated by rapid atmospheric adjustments to the radiative forcing based on 4xCO_2 CMIP6 simulations (Douville and John, 2020). Since AR5, many new studies applying the dual rapid adjustment and slow response framework show that global precipitation responses to different forcing agents are physically well understood (Fläschner et al., 2016; MacIntosh et al., 2016; Samset et al., 2016; Myhre et al., 2018a). Further confidence in the coupled processes involved are provided by simple models representing the energy budget and thermodynamic constraints that limit global mean evaporation to around 1.5% per °C (Siler et al., 2018b). This strengthens the physical link between energy budget and thermodynamic drivers of the global water cycle (Section 8.2.2.1).

[START FIGURE 8.3 HERE]

Figure 8.3: Schematic representation of fast and slow responses of the atmospheric energy balance and global precipitation to radiative forcing. The atmospheric energy budget ('baseline' panel) responds instantaneously to radiative forcings (1), leading to rapid atmospheric adjustments (2) and slower semi-rapid adjustments involving the land surface and vegetation that further modify atmospheric circulation patterns (3). This slow precipitation response to global mean surface air temperature (4) is quantified as the hydrological sensitivity, η, and the total precipitation response, including initial rapid adjustments, is termed the apparent hydrological sensitivity, η_a (a). The slow precipitation response over land and ocean develops over time (b–d). Large, filled arrows ('baseline'-4) depict fluxes or circulation change while small arrows (1-4) denote increases (↑) or decreases (↓) in variables (P is precipitation; L is atmospheric longwave radiative cooling, S is solar radiation absorption by the atmosphere; H is sensible heat flux; E is surface evaporative heat flux and T is temperature). (Adapted from Allan et al., 2020, Chapter 7 Figure 7.2 and Figure 8.1)

[END FIGURE 8.3 HERE]

Hydrological sensitivity (η) is defined as the linear change in global mean precipitation with global surface air temperature (GSAT) once rapid adjustments of the hydrological cycle to radiative forcings have occurred (Figure 8.3a). There is robust understanding and high agreement across idealised CO_2 forcing CMIP5 and CMIP6 experiments (Fläschner et al., 2016; Samset et al., 2018b; Pendergrass, 2020b) that η = 2.1-3.1 % per ºC (Figure 8.4). The magnitude of η depends primarily on atmospheric net radiative cooling which is controlled by thermal deepening of the troposphere (Jeevanjee and Romps, 2018) and limited by surface

[2] 5-95% confidence range estimates are quoted unless otherwise stated

ACCEPTED VERSION SUBJECT TO FINAL EDITING

evaporation and consequent atmospheric latent heat release and warming (Webb et al., 2018). Climate feedbacks (e.g. temperature lapse rate and clouds) that vary across models (Section 7.4; Section 3.8.2) also modulate the magnitude of η (O'Gorman et al., 2012; Fläschner et al., 2016; Richardson et al., 2018c). Uncertainty in η across CMIP5 models relating to deficiencies in representing low-altitude cloud feedbacks (Watanabe et al., 2018) and absorption of shortwave radiation by atmospheric water vapour (DeAngelis et al., 2015) do not apply well to CMIP6 simulations, the latter improvement explained by more accurate radiative transfer modelling (Pendergrass, 2020b).

Observed estimates of hydrological sensitivity (η = 3.2 ± 0.8 % per ºC) based on interannual variability (Allan et al., 2020) or responses to El Niño-Southern Oscillation (ENSO) of 9 % per ºC (Adler et al., 2017) are not suitable to assess the magnitude of η (Figure 8.4). This is because these relationships depend on amplifying feedbacks associated with ENSO-related cloud changes (Stephens et al., 2018b) that may not be relevant for longer term climate change. However, there is robust evidence and high agreement across observations, modelling and supporting physics that precipitation increases at a lower % per ºC rate than water vapour content in the global mean (Held and Soden, 2006b; Collins et al., 2013; Allan et al., 2020), implying an increased residence time of atmospheric water vapour (Hodnebrog et al., 2019b; Dijk et al., 2020). Increasing global precipitation, evaporation and moisture fluxes with warming thereby drive an intensification but not acceleration of the global water cycle (Sections 8.3.1.1 and 8.4.1.1).

The overall global mean rate of precipitation change per ºC of GSAT increase, **apparent hydrological sensitivity (η_a)**, is reduced compared to hydrological sensitivity by the direct influence of radiative forcing agents on the atmospheric energy balance. Rapid atmospheric adjustments that alter precipitation are primarily caused by GHGs and absorbing aerosols, with high agreement and medium evidence across idealised simulations (Fläschner et al., 2016; Samset et al., 2016). A range of rapid precipitation adjustments to CO_2 between models are also attributed to vegetation responses leading to a repartitioning of surface latent and sensible heat fluxes (DeAngelis et al., 2016). Values obtained from six CMIP5 models simulating the Last Glacial Maximum and pre-industrial period (η_a=1.6-3.0 % per ºC) are larger than for each corresponding 4xCO_2 experiment (η_a=1.3–2.6 % per ºC) due to differences in the mix of forcings, vegetation and land surface changes and a higher thermodynamic % per ºC evaporation scaling in the colder state (Li et al., 2013b). Updated estimates across comparable experiments from 22 CMIP5/CMIP6 models (Rehfeld et al., 2020) display a consistent range (η_a=1.7±0.6 % per ºC; Figure 8.4; Section 8.4.1.1). Confirming η_a in observations (Figure 8.4) is difficult due to measurement uncertainty, varying rapid adjustments to radiative forcing and unforced variability (Dai and Bloecker, 2019; Allan et al., 2020).

Climate drivers that instantaneously affect the surface much more than the atmospheric energy budget (such as solar forcing and sulphate aerosol) produce only a small rapid adjustment of the global water cycle and therefore larger η_a than drivers that immediately modulate the atmospheric energy budget such as GHGs and absorbing aerosol (Salzmann, 2016; Samset et al., 2016; Lin et al., 2018; Liu et al., 2018a). Thus, global precipitation appears more sensitive to radiative forcing from sulphate aerosols (2.8±0.7 % per ºC; $\eta_a \approx \eta$) than GHGs (1.4±0.5 % per ºC; $\eta_a < \eta$) while the response to black carbon aerosol can be negative (-3.5±5.0 % per ºC; $\eta_a << \eta$) due to strong atmospheric solar absorption (Samset et al., 2016). Therefore, artificially reducing surface absorbed sunlight through solar radiation modification strategies to mitigate GHG warming will not mitigate precipitation changes (see Sections 4.6.3.3; 6.4.7; 8.6.3). Aerosol-induced precipitation changes depend upon the type of aerosol species and their spatial distribution. Global mean precipitation increases after complete removal of present day anthropogenic aerosol emissions (see also Section 4.4.4) in four different climate models (η_a = 1.6-5.5% per ºC) are mainly attributed to sulphate aerosol as opposed to other aerosol species (Samset et al., 2018b). Idealised modelling studies show that sulphate aerosol increases over Europe produce a larger global precipitation response than an equivalent increase in aerosol burden or radiative forcing over Asia, explained by differences in cloud climatology and cloud-aerosol interaction (Kasoar et al., 2018; Liu et al., 2018c). The vertical profiles of black carbon and ozone further influence the magnitude of the rapid global precipitation response, yet are difficult to observe and simulate (Allen and Landuyt, 2014; MacIntosh et al., 2016; Stjern et al., 2017; Sand et al., 2020).

Hydrological sensitivity is generally lower over land but with a large uncertainty range (η = -0.1 to 3.0 % per ºC GSAT) relative to the oceans (η = 2.3 to 3.3 % per ºC) based on multi-model 4xCO_2 CMIP6 simulations

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Pendergrass, 2020b), broadly consistent with comparable CMIP5 experiments (Richardson et al., 2018c; Samset et al., 2018a). Suppressed hydrological sensitivity over land (Figure 8.3d; Figure 8.4) is associated with greater warming compared with the oceans, which alters atmospheric circulation and precipitation patterns (Saint-Lu et al., 2020). Also, since oceans supply much of the moisture to fuel precipitation over land, the slower ocean warming rate means there is insufficient moisture supplied to maintain continental relative humidity levels (Byrne and O'Gorman, 2018), which can inhibit convection (Chen et al., 2020b). Land surface feedbacks involving soil-vegetation-atmosphere coupling further drive continental drying (Berg et al., 2016; Kumar et al., 2016; Chandan and Peltier, 2020). The suppressed hydrological sensitivity is counteracted by rapid precipitation responses in most GHG-forced simulations, explained by greater surface downward longwave radiation due to CO_2 increases that rapidly warm the land, destabilize the troposphere and strengthen vertical motion in the short term (Chadwick et al., 2014; Richardson et al., 2016, 2018c). There is medium understanding of how land-sea warming contrast governs rapid precipitation responses based on idealised modelling that shows similar spatial patterns of precipitation response to radiative forcing from GHGs, solar forcing and absorbing aerosols (Xie et al., 2013; Samset et al., 2016; Kasoar et al., 2018). Rapid precipitation adjustments to CO_2 have been counteracted by cooling from anthropogenic aerosol increases over land (Box 8.1) but this compensation is expected to diminish as aerosol forcing declines (Richardson et al., 2018c). The fast and slow precipitation responses over global land globally combine during transient climate change (Figure 8.3d). This explains a consistent land and ocean mean precipitation increase in projections (Chapter 4, Table 4.3) but this is determined by a complex and model-dependent evolution of continental water cycle changes over space and time.

Increases in global precipitation over time, as the climate warms, are partly offset by the overall cooling effects of anthropogenic aerosol and by rapid atmospheric adjustments to increases in GHGs and absorbing aerosol. This explains why multi-decadal trends in global precipitation responses in the satellite era (Adler et al., 2017; Allan et al., 2020) are small and difficult to interpret given observational uncertainty, internal variability and volcanic forcings. The delayed warming effect of rising CO_2 concentration, combined with declining aerosol cooling, are expected to increase the importance of the slow temperature-related effects on the energy budget relative to the more rapid direct radiative forcing effects as transient climate change progresses (Shine et al., 2015; Salzmann, 2016; Myhre et al., 2018b).

In summary, there is *high confidence* that global mean evaporation and precipitation increase with global warming, but the estimated rate is model-dependent (*very likely* range of 2-3 % per ^{o}C) The global increase in precipitation is determined by a robust response to global surface temperature only (*very likely* 2–3% per 1°C) that is partly offset by fast atmospheric adjustments to the vertical profile of atmospheric heating by GHGs and aerosols. Global precipitation increases due to GHGs are offset by the well-understood overall surface radiative cooling effect by aerosols (*high confidence*). Over land, the average warming-related increase in precipitation is expected to be smaller than over the ocean due to increasing land-ocean thermal contrast and surface feedbacks, but the overall precipitation increase over land is generally reinforced by fast atmospheric responses to GHGs that strengthens convergence of winds (*medium confidence*). Global mean precipitation and evaporation increase at a lower rate than atmospheric moisture per ^{o}C of global warming (*high confidence*) leading to longer water vapour lifetime in the atmosphere and driving changes in precipitation intensity, duration and frequency and an overall intensification but not acceleration of the global water cycle.

8.2.2 Constraints on the regional water cycle

8.2.2.1 Thermodynamic constraints on atmospheric moisture fluxes

A warming climate drives increases in atmospheric moisture and horizontal moisture transport from the divergent to the convergent portions of the atmospheric circulation (including storm systems, the tropical rain belt and monsoons) that on average amplifies existing precipitation minus evaporation (P-E) patterns (Held and Soden, 2006a). Increased latent heat transports in high latitudes also contribute to polar amplification of warming (Section 7.4.4.1). Although convergent parts of the atmospheric circulation are expected to become wetter (in terms of increasing P-E) and net evaporative regions drier (increasing E-P)

ACCEPTED VERSION SUBJECT TO FINAL EDITING

these regions are not geographically and seasonally fixed and their location and timing are expected to alter (Section 8.2.2.2). Atmospheric and ocean circulation changes overall decrease the amplification of P-E and salinity patterns. Paleoclimate evidence confirms that during the Last Glacial Maximum (21–19 thousand years ago), zonal mean changes were roughly in agreement with thermodynamic expectations (Li et al., 2013b). However regional changes can be dominated by dynamics, including responses to the large Northern Hemisphere ice sheets (DiNezio and Tierney, 2013; Bhattacharya et al., 2017b; Scheff et al., 2017; D'Agostino et al., 2019; Lowry and Morrill, 2019) such that altered P-E patterns are not well described by thermodynamic drivers (Oster et al., 2015; Lora, 2018; Morrill et al., 2018).

There is robust evidence and high agreement across thermodynamics, detailed modelling and observations that amplification of P-E patterns occurs over the oceans (Figure 8.5a) with an associated "fresh gets fresher, salty gets saltier" signature in ocean salinity (Sections 2.3.3.2 and 3.5.2). This amplification is moderated by proportionally larger increases in sub-tropical ocean evaporation and weakening of the tropical circulation (Section 8.2.2.2), an expectation supported by observations (Skliris et al., 2016) and process understanding (Yang and Roderick, 2019). Thermodynamics explain a smaller low latitude evaporation increase (1% per ^{o}C) than in high latitudes (5% per ^{o}C) with changes in surface radiation, boundary layer adjustments and ocean heat uptake playing a secondary role, based on idealised modelling (Siler et al., 2018b). Increased evaporation from warmer oceans and lakes is exacerbated by the loss of surface ice in some regions (Bintanja and Selten, 2014; Laîné et al., 2014; Wang et al., 2018d; Sharma et al., 2019; Woolway et al., 2020). This can generate a more local moisture source for precipitation, for example in northwest Greenland during non-summer months since the 1980s (Nusbaumer et al., 2019), though moisture transport changes can counteract this effect (Nygård et al., 2020). Ocean stratification due to heating of the upper layers through radiative forcing has been identified as a mechanism that further amplifies surface salinity patterns beyond the responses driven by water cycle changes alone (Zika et al., 2018).

[START FIGURE 8.4 HERE]

Figure 8.4: Estimate (5-95% range) of the increase in precipitation and its extremes with global mean surface warming. Global time averaged precipitation changes (left) are based on responses to increasing CO_2 (apparent hydrological sensitivity, η_a) and the temperature-dependent component (hydrological sensitivity, η) based on GCM experiments and including the land (L) and ocean (O) components (Fläschner et al., 2016; Richardson et al., 2018c; Samset et al., 2018a; Pendergrass, 2020b; Rehfeld et al., 2020) and observational estimates (GPCP/HadCRUTv4.6) using trends (1988-2014) as a proxy for η_a and interannual variability as a proxy for η with 90% confidence range accounting for statistical uncertainty only (Adler et al., 2017; Allan et al., 2020). For extreme precipitation, assessment is for 24 hour 99.9th percentile or annual maximum extremes from GCMs (Fischer and Knutti, 2015; Pendergrass et al., 2015; Borodina et al., 2017; Pfahl et al., 2017; Sillmann et al., 2017), regional climate models (RCMs) (Bao et al., 2017), an observationally constrained tropical estimate (O'Gorman, 2012) and estimates from observed changes (Westra et al., 2013; Donat et al., 2016; Borodina et al., 2017; Sun et al., 2020; Zeder and Fischer, 2020). For hourly and sub-hourly extremes observed changes (Barbero et al., 2017; Guerreiro et al., 2018) and high resolution models including RCM and cloud resolving models (CRMs) are assessed (Ban et al., 2015; Prein et al., 2017; Haerter and Schlemmer, 2018; Hodnebrog et al., 2019a; Lenderink et al., 2019). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.4 HERE]

Since AR5, numerous studies have confirmed that changes in P-E with warming over land cannot be interpreted simply as a "wet regions get wetter, dry regions gets drier" response (Chadwick et al., 2013; Greve et al., 2014; Roderick et al., 2014; Byrne and O'Gorman, 2015; Scheff and Frierson, 2015). Firstly, P-E is a simplistic diagnostic of the water cycle that inadequately describes "dryness" or aridity (Fu and Feng, 2014; Roderick et al., 2014; Greve and Seneviratne, 2015; Scheff and Frierson, 2015; Greve et al., 2019; Vicente-Serrano et al., 2020b). Secondly, terrestrial P-E is generally positive and balanced by surface runoff and percolation into subsurface soils and aquifers (Figure 8.1). As a result, the simple thermodynamic

ACCEPTED VERSION SUBJECT TO FINAL EDITING

scaling (Figure 8.5b) predicts that P-E over land will become more positive (wetter) with warming (Greve et al., 2014; Roderick et al., 2014; Byrne and O'Gorman, 2015). This is not necessarily true, however, in the dry seasons and regions where terrestrial water is lost to the atmosphere and exported (Sheffield et al., 2013; Kumar et al., 2015; Keune and Miralles, 2019). Thirdly, regional P-E patterns over land are affected by changes in atmospheric circulation, oceanic moisture supply and land surface feedbacks. As the land warms more than oceans, spatial gradients in temperature and relative humidity influence moisture supply and reduce P-E over some land regions, such as southern Chile and Argentina around 30-50°S as captured by an extended thermodynamic scaling (Figure 8.5b). Drying of soils can be amplified by vegetation responses (Berg et al., 2016; Byrne and O'Gorman, 2016; Lambert et al., 2017) but limited by atmospheric circulation feedbacks (Zhou et al., 2021). Changes in soil moisture and rainfall intensity (Sections 8.2.3.2-8.2.3.3) can alter the partitioning of precipitation between evaporation and runoff, further complicating terrestrial P-E responses (Short Gianotti et al., 2020).

The strong physical basis for regionally and seasonally dependent responses of P-E and the expectation for an increasing contrast between wet and dry seasons and weather regimes is supported by high agreement across multiple observational and CMIP5/CMIP6 modelling studies (Liu and Allan, 2013; Kumar et al., 2015; Polson and Hegerl, 2017; Ficklin et al., 2019; Deng et al., 2020; Schurer et al., 2020). Increased moisture transports into storm systems, monsoons and high latitudes increase the intensity of wet events (Section 8.2.3.2), while stronger atmospheric evaporative demand with warming (Scheff and Frierson, 2014; Vicente-Serrano et al., 2018; Cook et al., 2019) is an important mechanism for intensifying dry events (Section 8.2.3.3) and decreasing soil moisture over many subtropical land regions. However, aridification is modulated regionally by poleward migration of the sub-tropical dry zones and an increasing land-ocean temperature contrast that drives declining relative humidity (Section 8.2.2.2).

To summarise, increased moisture transport from evaporative oceans to high precipitation regions of the atmospheric circulation will drive amplified P-E and salinity patterns over the ocean (*high confidence*) while more complex regional changes are expected over land. Greater warming over land than ocean alters atmospheric circulation patterns and on average reduces continental near-surface relative humidity which along with vegetation feedbacks can contribute to regional decreases in precipitation (*high confidence*). Based on an improved understanding of thermodynamic drivers since AR5 and multiple lines of evidence, there is *high confidence* that very wet or dry seasons and weather patterns will intensify in a warming climate such that wet spells become wetter and dry spells drier.

8.2.2.2 Large-scale responses in atmospheric circulation patterns

Responses of the large-scale atmospheric circulation to a warming climate are not as well understood as thermodynamic drivers (Shepherd, 2014). AR5 identified robust features including a weakening and broadening of tropical circulation with poleward movement of tropical dry zones and mid-latitude jets (Collins et al., 2013). These can dominate regional water cycle changes, affecting the availability of fresh water and the occurrence of climate extremes. Atmospheric circulation changes generally dominate the spatial pattern of rapid precipitation adjustments (Section 8.2.1) to different forcing agents in the tropics (Bony et al., 2013; He and Soden, 2015; Richardson et al., 2016, 2018c; Tian et al., 2017; Li et al., 2018b). Radiative forcing with heterogeneous spatial patterns such as ozone and aerosols (including cloud interactions; Box 8.1; Section 6.4.1) drive substantial responses in regional atmospheric circulation through uneven heating and cooling effects (Liu et al., 2018c; Wilcox et al., 2018b; Dagan et al., 2019b). Changes in atmospheric circulation are also driven by slower, evolving patterns of warming and associated changes in temperature and moisture gradients (Bony et al., 2013; Samset et al., 2016, 2018a; Ceppi et al., 2018; Ma et al., 2018). There is strong evidence that large regional water cycle changes arise from the atmospheric circulation response to radiative forcings and associated SST pattern evolution but low agreement in the sign and magnitude (Chadwick et al., 2016a). The role of prolonged weather regimes in determining wet and dry extremes is also better understood since AR5 (Kingston and McMecking, 2015; Schubert et al., 2016; Richardson et al., 2018a; Barlow et al., 2019). Advances in knowledge of expected large-scale dynamical responses of the water cycle are further assessed in this section (see also Figure 8.21).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Long-term weakening of the tropical atmospheric overturning circulation is expected as climate warms in response to elevated CO_2 (Collins et al., 2013). A weaker circulation is required to reconcile global mean low-level water vapour increases (around 7% per ºC) with the smaller global precipitation responses of about 1-3% per ºC (Section 8.2.1). The slowdown can occur in both the Hadley and Walker circulations, but occurs preferentially in the Walker circulation in most climate models (Vecchi and Soden, 2007) but this response has been questioned on the basis of model bias in east Pacific SST (Seager et al., 2019a). Weakening is expected to drive P-E decreases over the western Pacific and increases over the eastern Pacific. However, the driving mechanisms for Walker circulation weakening differ to those involved in determining ENSO variability, so it is too simplistic to interpret changes as an El Niño pattern of regional hydrological cycle extremes (Sohn et al., 2019). Internal variability is also capable of temporarily strengthening the Walker circulation (Section 2.3.1.4.1)(L'Heureux et al., 2013; Chung et al., 2019) while regional responses depend on the pattern of warming (Sandeep et al., 2014).

Model simulations show a stronger Pacific Walker circulation during the Last Glacial Maximum in response to a cooler climate (consistent with an expected weakening in a warmer climate), but a weaker Indian Ocean east-west circulation in response to the exposure of the Sunda and Sahul shelves due to lowered sea level (DiNezio et al., 2011). The latter effect is detectable in proxies for hydroclimate, as well as salinity and sea-surface temperature (DiNezio and Tierney, 2013; DiNezio et al., 2018). More relevant to future warming is the mid-Pliocene period (3 million years ago), the last time the Earth experienced CO_2 levels comparable to present (see Cross-Chapter Box 2.4). Sea surface temperature (SST) reconstructions show a weakening of the Pacific zonal gradient and a pattern of warmth consistent with a weaker Walker cycle response (Corvec and Fletcher, 2017; Tierney et al., 2019; McClymont et al., 2020). Although the Pliocene SST pattern and wet subtropics contrast with present conditions (Burls and Fedorov, 2017), the paleoclimate record strengthens evidence that a warmer climate is associated with a weaker Walker circulation (Cross-Chapter Box 2.4; Section 3.3.3).

Since AR5, weakening of the tropical circulation has been explained as a rapid response to increasing CO_2 concentrations and slower response to warming and evolving SST patterns (He and Soden, 2017; Xia and Huang, 2017; Shaw and Tan, 2018; Chemke and Polvani, 2020). Large-scale tropical circulation weakens by 3-4% in a rapid response to a quadrupling of CO_2 concentrations (Plesca et al., 2018), which suppresses tropospheric radiative cooling, particularly in sub-tropical ocean subsidence regions (Bony et al., 2013; Merlis, 2015; Richardson et al., 2016). The resulting increased atmospheric stability explains the rapid weakening of the Walker circulation (Wills et al., 2017) and Northern Hemisphere Hadley Cell (Chemke and Polvani, 2020). Subsequent surface warming contributes up to a 12% slowing of circulation for a uniform 4ºC SST increase, driven by thermodynamic decreases in temperature lapse rate (Plesca et al., 2018).

The regional Intertropical Convergence Zone (ITCZ) position, width and strength determine the location and seasonality of the tropical rain belt. Since AR5, multiple studies have linked cross-equatorial energy transport to the mean ITCZ position (Donohoe et al., 2013; Frierson et al., 2013; Bischoff and Schneider, 2014; Boos and Korty, 2016; Loeb et al., 2016; Adam et al., 2018; Biasutti and Voigt, 2019). Multi-model studies agree that aerosol cooling in the Northern Hemisphere led to a southward shift in the ITCZ and tropical precipitation after the 1950s up to the 1980s that is linked with the 1980s Sahel drought (Box 8.1; Section 8.3.2.4; Section 10.4.2.1). In particular, aerosol-cloud interaction was identified as a potentially important driver of this shift (Chung and Soden, 2017) but this is uncertain since observations suggest that models may overestimate (Malavelle et al., 2017; Toll et al., 2017) or underestimate (Rosenfeld et al., 2019) the aerosol cloud-mediated cooling effects. In addition, greenhouse gas forcing has been invoked in explaining much of the increase in Sahel precipitation since the 1980s through enhanced meridional temperature gradient, with only a secondary role for aerosol (Dong and Sutton, 2015).

Understanding of how ITCZ width and strength respond to a warming climate has improved since AR5 (Byrne and Schneider, 2016; Harrop and Hartmann, 2016; Popp and Silvers, 2017; Dixit et al., 2018; Zhou et al., 2020). Studies suggest that convection gets stronger and more focused within the core of the ITCZ (Lau and Kim, 2015; Byrne et al., 2018). This leads to drying on the equatorward edges of the ITCZ and a moistening tendency in the ITCZ core (Byrne and Schneider, 2016). Feedbacks involving clouds have been identified as an important mechanism leading to tightening and strengthening of the ITCZ (Popp and Silvers,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2017; Su et al., 2017, 2019, 2020; Talib et al., 2018). Stronger ascent in the core amplifies the "wet get wetter" response while reduced moisture inflow near the ITCZ edges reduces this response below the 7% per ^{o}C thermodynamic increase in moisture transport. Thus, there is a range of evidence and medium agreement for strengthening and contraction of the ITCZ with warming that sharpens contrasts between wet and dry regimes. However, understanding of how the regional ITCZ location responds in a warming climate is not robust (Section 8.4.2.1) with *limited evidence* of distinct regional responses to GHG forcing including a northward shift over eastern Africa and the Indian Ocean and a southward shift in the eastern Pacific and Atlantic oceans (Mamalakis et al., 2021). Paleoclimate evidence highlights the distinct regional ITCZ responses to hemispheric asymmetry in volcanic and orbital forcing (McGee et al., 2014; Boos and Korty, 2016; Colose et al., 2016; Denniston et al., 2016; PAGES Hydro2K Consortium, 2017; Singarayer et al., 2017; Atwood et al., 2020) and rapid (>1^{o} latitude over decades) shifts in the ITCZ and regional monsoons in response to AMOC collapse cannot be ruled out (Sections 8.6.1.1 and 5.1.3).

Monsoons are key components of the tropical overturning circulation that can be understood as a balance between net energy input (e.g. radiative and turbulent fluxes) and the export of moist static energy. This is determined by contrasting surface heat capacity between ocean and land and modified through changes in atmospheric dynamics, tropical tropospheric stability and land surface properties (Jalihal et al., 2019). Thermodynamic increases in moisture transport are expected to increase monsoon strength and area (Christensen et al., 2013). Since AR5, evidence continues to demonstrate that monsoon circulation is sensitive to spatially varying radiative forcing by anthropogenic aerosols (Hwang et al., 2013; Allen et al., 2015b; Li et al., 2016c) and GHGs (Dong and Sutton, 2015). Changes in SST patterns also play a role (Guo et al., 2016; Zhou et al., 2019b; Cao et al., 2020) by altering cross-equatorial energy transports and land-ocean temperature contrasts. This evidence continues to support a thermodynamic strengthening of monsoon precipitation that is partly offset by slowing of the tropical circulation but with *weak evidence* and *low agreement* for regional aspects of circulation changes. Disagreement between paleo-climate and modern observations, physical theory and numerical simulations of global monsoons have been partly reconciled (Section 3.3.3.2) through improved understanding of regional processes (Harrison et al., 2015; Bhattacharya et al., 2017a, 2018; Biasutti et al., 2018; D'Agostino et al., 2019; Jalihal et al., 2019; Seth et al., 2019), although interpreting past changes in the context of future projections requires careful account of differing forcings and feedbacks (D'Agostino et al., 2019). Assessment of past changes and future projections in regional monsoons are provided in Sections 2.3.1.4.2, 8.3.2.4 and 8.4.2.4.

Since AR5, understanding of poleward expansion of the Hadley Cells has improved (Section 2.3.1.4.1) but its role in subtropical drying is limited to the zonal mean and dominated by ocean regions (Byrne and O'Gorman, 2015; Grise and Polvani, 2016; He and Soden, 2017; Schmidt and Grise, 2017; Siler et al., 2018a; Chemke and Polvani, 2019; Grise and Davis, 2020). Over subtropical land, evolving SST patterns and land-ocean warming contrasts, that are partly explained by rapid responses to CO_2 increases, can dominate aspects of the atmospheric circulation response (Byrne and O'Gorman, 2015; He and Soden, 2015; Chadwick et al., 2017; Yang et al., 2020a) and resultant regional water cycle changes, particularly for projected drying in semi-arid, winter-rainfall dominated sub-tropical climates (Deitch et al., 2017; Brogli et al., 2019; Seager et al., 2019b; Zappa et al., 2020). Poleward expansion of the tropical belt is expected to drive a corresponding shift in mid-latitude storm tracks, but the controlling mechanisms differ between hemispheres. Southern Hemisphere expansion is driven by GHG forcing and amplified by stratospheric ozone depletion, while weaker Northern Hemisphere expansion in response to GHG forcing is modulated by tropospheric ozone and aerosol forcing, particularly black carbon (Davis et al., 2016; Grise et al., 2019; Watt-Meyer et al., 2019; Zhao et al., 2020). However, internal variability is found to dominate observed responses in the Northern Hemisphere, precluding attribution to radiative forcing (D'Agostino et al., 2020b). Paleoclimate evidence of poleward expansion and weakening of westerly winds in both hemispheres in the warmer Pliocene is linked to reduced equator to pole thermal gradients and ice volume (Abell et al., 2021).

The influence of amplified Arctic warming on mid-latitude regional water cycles is not well understood based on simple physical grounds due to the large number of competing physical processes (Cross Chapter Box 10.1). The thermal gradient between polar and lower latitude regions decreases at low levels due to Arctic warming amplification. However, at higher altitudes, the corresponding thermal gradient increases with warming due to cooling of the Arctic stratosphere and this is consistent with a strengthening of the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

winter jet stream in both hemispheres, yet there is *low agreement* on the precise mechanisms (Vallis et al., 2015; Vihma et al., 2016). Changes in the strength of the polar stratospheric vortex can also alter the mid-latitude circulation in winter, but responses are not consistent across models (Oudar et al., 2020a). Nevertheless, thermodynamic strengthening of moisture convergence into weather systems and polar regions is robust (Section 8.2.2.1) and remains valid despite weak understanding of atmospheric circulation change.

In summary, there is *high confidence* that altered atmospheric wind patterns in response to radiative forcing and evolving surface temperature patterns will affect the regional water cycle in most regions. Mean tropical circulation is expected to slow with global warming (*high confidence*) but temporary multi-decadal strengthening is possible due to internal variability (*medium confidence*). Slowing of the tropical circulation reduces the meridional P-E gradient over the Pacific and can partly offset thermodynamic amplification of P-E patterns and strengthening of monsoons (*high confidence*) but regional characteristics of tropical rain belt changes are not well understood. There is *medium confidence* in processes driving strengthening and tightening of the ITCZ that increase the contrasts between wet and dry tropical weather regimes and seasons. There is *high confidence* in understanding of how radiative forcing and global warming drive a poleward expansion of the subtropics and mid-latitude stormtracks but only *low confidence* in how poleward expansion influences drying of sub-tropical and mid-latitude climates. There is *low confidence* in understanding how Arctic warming amplification affects mid-latitude regional water cycles but *high confidence* that thermodynamic strengthening of precipitation within weather systems and in monsoons and polar regions is robust to large-scale circulation changes.

8.2.3 Local-scale physical processes affecting the water cycle

Processes operating at local scales are capable of substantially modifying the regional water cycle. This section assesses the development in understanding of processes affecting the atmosphere, surface and subsurface, including cryosphere and biosphere interactions and the direct impacts of human activities.

8.2.3.1 Hydrological processes related to ice and snow

Declining ice sheet mass, glacier extent and Northern Hemisphere sea ice, snow cover and permafrost (Collins et al., 2013; Vaughan et al., 2013) is an expected consequence of a warming climate (Sections 2.3.2; 3.4; 4.3.2.1; 9.3-9.5). A decline in mountain snow cover and increased snow and glacier melt will alter the amount and timing of seasonal runoff in mountain regions (Sections 3.4.2; 3.4.3; 9.5). Earlier and more extensive winter and spring snowmelt (Zeng et al., 2018a) can reduce summer and autumn runoff in snow dominated river basins of mid-high latitudes of the Northern Hemisphere (Rhoades et al., 2018; Blöschl et al., 2019). Since AR5, an earlier but less rapid snowmelt has been explained by reduced winter snowfall and less intense solar radiation earlier in the season (Musselman et al., 2017; Wu et al., 2018b; Grogan et al., 2020). Reduced snow cover also increases energy available for evaporation, which can dominate declining river discharge based on modelling of the Colorado River (Milly and Dunne, 2020). An increase in the fraction of precipitation falling as rain versus snow can lead to declines in both streamflow and groundwater storage in regions where snow melt is the primary source of recharge (Earman and Dettinger, 2011; Berghuijs et al., 2014). Such regions include western South America and western North America, semi-arid regions which rely on snowmelt from high mountain chains (Ragettli et al., 2016; Milly and Dunne, 2020). Rain-on snow melt events reduce at lower altitudes due to declining snow cover but increased at higher altitudes where snow tends to be replaced by rain based on observations and modelling (Musselman et al., 2018; Pall et al., 2019), thereby altering seasonal and regional characteristics of flooding (Section 11.5).

Seasonal meltwater from high mountain glaciers in Asia (see Cross-Chapter Box 10.4) supply the basic needs of 221±97 million people (Pritchard, 2019; Immerzeel et al., 2020). Glacier-melt in response to warming can initially lead to increased runoff volumes, especially in peak summer flows, but they will eventually decline as most glaciers continue to shrink. SROCC concluded there is *high confidence* that the peak runoff has already been passed for some smaller glaciers (Hock et al., 2019b). Increased precipitation and glacier melt can also contribute to rising lake levels and flood hazards in regions such as the inner

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Tibetan Plateau, Patagonia, Peru, Alaska and Greenland (Lei et al., 2017; Shugar et al., 2020; Stuart-Smith et al., 2020). Since AR5, evidence from multiple locations (New Zealand, Greenland, Antarctica) shows that intrusions of warm, moist air are important in controlling glacier mass balance, the likelihood of extreme ablation or snowfall events depending on air temperature (Gorodetskaya et al., 2014; Mackintosh et al., 2017; Mattingly et al., 2018; Oltmanns et al., 2018; Little et al., 2019; Wille et al., 2019; Adusumilli et al., 2021). Sensible heating from warm air and increased longwave radiation from atmospheric moisture and low clouds drive melt events (Stuecker et al., 2018).

Reductions in snow, freshwater ice and permafrost affect terrestrial hydrology. Permafrost degradation reduces soil ice and alters the extent of thermokarst lake coverage (Section 9.5.2; SROCC (Meredith et al., 2019b)). A lag between current climate change and permafrost degradation is expected, given the slow response rates in frozen ground and the fact that snow cover insulates soil from sensible heat exchanges with the air above (Hoegh-Guldberg et al., 2018; García-García et al., 2019; Soong et al., 2020). Post-wildfire areas are also linked with permafrost degradation in the Arctic based on satellite observations (Yanagiya and Furuya, 2020). An increase in spring rainfall can increase heat advection by infiltration, exacerbating permafrost thaw and leading to increased methane emissions (Neumann et al., 2019) (Section 5.4.7). Increased heat transport by Arctic rivers can also contribute to earlier sea ice melt (Park et al., 2020).

In summary, it is *virtually certain* that warming will cause a loss of frozen water stores, except in areas where temperatures remain below 0ºC for most of the year. There is *high confidence* that warming and reduced snow volume drives an earlier snowmelt, leading to seasonally dependent changes in streamflow. There is *medium confidence* that weaker sunlight earlier in the season can reduce the rate of snowmelt. Melting of snowpack or glaciers can increase stream flow in high latitude and high-altitude catchments until frozen water reserves are depleted (*high confidence*). There is *high confidence* that warm, moist airflows and associated precipitation dominate glacier mass balance in some regions (New Zealand, Greenland, Antarctica).

8.2.3.2 Processes determining heavy precipitation and flooding

Evidence that heavy precipitation events (from sub-daily up to seasonal timescales) intensify as the planet warms has strengthened since AR5 (Box 11.1; Section 11.4; Cross Chapter Box 3.2) based on improved physical understanding, extensive modelling and increasing observational corroboration (O'Gorman, 2015; Fischer and Knutti, 2016; Neelin et al., 2017). There is *robust evidence*, with *medium agreement* across a range of modelling and observational studies, of thermodynamic intensification of wet seasons (Chou et al., 2013; Liu and Allan, 2013; Dunning et al., 2018; Lan et al., 2019; Zhang and Fueglistaler, 2019). Extreme daily precipitation is expected to increase at close to the 7%/ºC increase in the near-surface atmospheric moisture holding capacity determined by the Clausius-Clapeyron equation (Section 11.4, Figure 8.4), with *limited evidence* that higher rates apply for shorter duration precipitation events (Formayer and Fritz, 2017; Lenderink et al., 2017; Ali et al., 2018; Guerreiro et al., 2018; Burdanowitz et al., 2019; Zhang et al., 2019b). However, observed estimates sample multiple synoptic weather states, mixing thermodynamic and dynamic factors, so are not directly relatable to climate change responses (Bao et al., 2017; Drobinski et al., 2018). The contrasting spatial scales sampled by the observations and models (from global to cloud resolving) explain the large range of daily and sub-daily precipitation scaling with temperature assessed in Figure 8.4.

[START FIGURE 8.5 HERE]

Figure 8.5: Zonally-averaged annual mean changes in precipitation minus evaporation (P-E) over (a) ocean and (b) land between the historical (1995–2014) and SSP2-4.5 (2081–2100) CMIP6 simulations (blue lines, an average of the CanESM5 and MRI-ESM2-0 models). Dashed lines show estimated P-E changes using a simple thermodynamic scaling (Held and Soden, 2006b); dotted lines show estimates using an extended scaling (Byrne and O'Gorman, 2016). All curves have been smoothed in latitude using a three grid-point moving-average filter. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[END FIGURE 8.5 HERE]

Since AR5, advances in understanding the expected changes in intense rainfall at the sub-daily time-scale (Section 11.4, Figure 8.4) are provided by idealised or high resolution model experiments and observations (Westra et al., 2014; Fowler et al., 2021). There is *robust evidence* from simplified calculations, convection resolving models and observations that thermodynamics drives an increase in convective available potential energy (CAPE) with warming and therefore the intensity of convective storms (Singh and O'Gorman, 2013; Romps, 2016; Barbero et al., 2019). Also, declining relative humidity over land (Sections 2.3.1.3.2; 8.2.2.1) increases lifting condensation level, thereby delaying but intensifying convective systems (Louf et al., 2019; Chen et al., 2020b). Larger systems are linked with increasing tropopause height (Lenderink et al., 2017) that can also amplify storm precipitation (Prein et al., 2017). However, the heaviest rainfall is not necessarily associated with the most intense (deepest) storms based on satellite data (Hamada et al., 2015; Hamada and Takayabu, 2018). Precipitation intensification can exceed thermodynamic expectations where and when additional latent heating invigorates individual storms (Section 11.4.1) as implied by *medium agreement* across modelling and observational studies (Berg et al., 2013; Molnar et al., 2015; Scoccimarro et al., 2015; Prein et al., 2017; Zhou and Wang, 2017; Nie et al., 2018; Zhang et al., 2018f; Kendon et al., 2019). This intensification depends on time of day, based on convection-permitting simulations (Meredith et al., 2019a).

Intensification of sub-daily rainfall is inhibited in regions and seasons where available moisture is limited (Prein et al., 2017). However, a fixed threshold temperature above which precipitation is limited by moisture availability is not supported by modelling evidence (Neelin et al., 2017; Prein et al., 2017). Enhanced latent heating within storms can also suppress convection at larger-scales due to atmospheric stabilization as demonstrated with high resolution, idealised and large ensemble modelling studies (Loriaux et al., 2017; Chan et al., 2018; Nie et al., 2018; Tandon et al., 2018; Kendon et al., 2019). Stability is also increased by the direct radiative heating effect of higher CO_2 concentrations (Baker et al., 2018) and influenced by aerosol effects on the atmospheric energy budget and cloud development (Box 8.1). Since AR5, modelling evidence shows increases in convective precipitation extremes are limited by droplet/ice fall speeds (Singh and O'Gorman, 2014; Sandvik et al., 2018) but these processes are only crudely represented (Tapiador et al., 2019b). Idealised regional and coupled global models combined with *limited* observational *evidence* shows that instantaneous precipitation extremes are sensitive to microphysical processes while daily extremes are determined more by the degree of convective aggregation (Bao and Sherwood, 2019; Pendergrass, 2020a).

Dynamical changes modify and can dominate thermodynamic drivers of local rainfall and flood hazard change (Box 11.1). For example, increased land-ocean temperature gradients (Section 8.2.2.2) explain more intense rain from convective systems over the Sahel based on satellite data since the 1980s (Taylor et al., 2017) and dynamical feedbacks can invigorate active to break phase transition over India (Karmakar et al., 2017; Roxy et al., 2017). Satellite data shows long-lived, organised mesoscale convective systems contribute disproportionally to extreme tropical precipitation (Roca and Fiolleau, 2020). Since AR5, the spatial variability in soil moisture has been linked with the timing and location of convective rainfall by altering the partitioning between latent and sensible heating. This was demonstrated for the Sahel, Europe and India in observations (Taylor et al., 2013a; Taylor, 2015; Petrova et al., 2018; Barton et al., 2019; Klein and Taylor, 2020) but depends on the moisture convergence regime (Welty et al., 2020). Only high resolution convection permitting models can capture the sub-grid scale mechanisms for convective initiation (Taylor et al., 2013a; Moon et al., 2019a). There is *medium evidence* that greater tropical cyclone rainfall totals can be caused by dynamical feedbacks (Chauvin et al., 2017) and slower propagation speed as tropical circulation weakens (Kossin, 2018). These processes amplify the thermodynamic intensification of rainfall (Section 11.7.1.2), yet observational support is weak (Chan, 2019; Lanzante, 2019; Moon et al., 2019b; Knutson et al., 2020). Slower decay following landfall, explained by larger stores of heat and moisture at higher SSTs, can also amplify rainfall amount based on observations and modelling (Li and Chakraborty, 2020). Rainfall intensity from the outer rain bands of tropical cyclones is also increased by aerosol-cloud interactions (Box 8.1).

The amount and intensity of rainfall within extratropical storms is expected to increase with atmospheric moisture. This is particularly evident for atmospheric rivers (see glossary) and research since AR5 has confirmed their link with flooding and terrestrial water storage (Froidevaux and Martius, 2016; Paltan et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2017; Waliser and Guan, 2017; Adusumilli et al., 2019; Ionita et al., 2020; Payne et al., 2020). There is *robust evidence* based on simple physics and detailed modelling that extra-tropical cyclone rainfall, including atmospheric river events, will intensify through increased atmospheric moisture flux (Lavers et al., 2013; Ramos et al., 2016; Yettella and Kay, 2017; Espinoza et al., 2018b; Algarra et al., 2020; Xu et al., 2020; Zavadoff and Kirtman, 2020; Zhao, 2020), although changes in dynamical aspects will modify responses regionally (section 8.4.2.8). For example, stronger latitudinal temperature gradients in the high latitude upper troposphere drive increased extra-tropical storm speed around 30-70°N based on CMIP5 simulations (Dwyer and O'Gorman, 2017), causing reduced precipitation accumulation.

The response of flood hazard to changing rainfall characteristics depends on time and space scale and the nature of the land surface (Section 11.5.1; FAQ 8.2). Sustained and heavy rainfall can lead to widespread flooding and landslides while intensification of short-duration intense rainfall can increase the severity and frequency of flash flooding (Marengo et al., 2013; Chan et al., 2016; Gariano and Guzzetti, 2016; Sandvik et al., 2018). Flooding events in many tropical regions (e.g. north west South America, southern Africa and Australasia) are associated with ENSO variability (Emerton et al., 2017; Takahashi and Martínez, 2019; Pabón-Caicedo et al., 2020) and amplified by thermodynamic increases in water vapour. Flood hazard from heavy rainfall is modulated by snowmelt (Section 8.2.3.1), vegetation characteristics (Murphy et al., 2020; Page et al., 2020) and direct human intervention (Section 8.2.3.4; FAQ 8.2) but also can be compounded by sea level rise (Sections 4.3.2.2; 9.6.4) in coastal and delta regions (Bevacqua et al., 2019; Ganguli and Merz, 2019; Eilander et al., 2020). Antecedent soil moisture conditions are an important modulator of flooding (Section 11.5.1) but become less important for smaller catchments and for more severe floods (Wasko and Nathan, 2019). Depleted soil moisture after more intense dry seasons (Section 8.2.2.1) can allow greater uptake of wet season rainfall before soils saturate. Since AR5, evidence confirms that more intense rainfall increases the proportion of runoff and reservoir recharge relative to infiltration into the soil (Eekhout et al., 2018; Yin et al., 2018). More intense but less frequent storms (Kendon et al., 2019) favour focused groundwater recharge through leakage from surface waters (Taylor et al., 2013b; Cuthbert et al., 2019a) and runoff and flash flooding where the percolation capacity of the soil is exceeded (Yin et al., 2018).

Increased severity of flooding on larger, more slowly-responding rivers is expected as precipitation accumulations increase during persistent wet events over a season. This can occur where atmospheric blocking patterns repeatedly steer extra tropical cyclones across large river catchments, as identified for Northern Hemisphere mid-latitudes and Asia (Takahashi et al., 2015; Lenggenhager et al., 2018; Pfleiderer et al., 2018; Zhou et al., 2018; Blöschl et al., 2019; Nikumbh et al., 2019; Zanardo et al., 2019), although groundwater flooding and antecedent conditions including soil moisture and snow melt also play a role (Muchan et al., 2015; Berghuijs et al., 2019). Increased atmospheric moisture amplifies the severity of these events when they occur in a warmer climate, yet drivers of change in the occurrence of blocking patterns, stationary waves and jet stream position are not well understood (Section 8.2.2.2, Cross Chapter Box 10.1).

In summary, there is *very high confidence* that heavy precipitation events will become more intense in a warming climate. There is *high confidence* that increased moisture and its convergence within extra-tropical and tropical cyclones and storms will increase rainfall totals during wet events at close to the 7% per °C thermodynamic response, with *low confidence* of higher rates for sub-daily intensities. There is *medium confidence* that more intense but less frequent rainfall increases the proportion of rainfall leading to surface runoff and focused groundwater recharge from temporary water bodies. There is *low confidence* in how the frequency of flooding will change regionally as it is strongly dependent on catchment characteristics, antecedent conditions and how atmospheric circulation systems respond to climate change, which is less certain than thermodynamic drivers (Section 11.5). However, there is *high confidence* that increases in precipitation intensity and amount during very wet events (from sub-daily up to seasonal time-scales) will intensify severe flooding when these extremes occur.

8.2.3.3 Drivers of aridity and drought

Regional changes in aridity – broadly defined as a deficit of moisture – are expected to occur in response to anthropogenic forcings as a consequence of shifting precipitation patterns, warmer temperatures, changes in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

cloudiness (affecting solar radiation), declining snowpack, changes in winds and humidity, and vegetation cover (Figure 8.6). Evapotranspiration (see Annex VII: Glossary) is a key component of aridity, and is composed of two main processes: evaporation from soil, water and vegetation surfaces; and transpiration, the exchange of moisture between plants and atmosphere through plant stomata. On a global level, warmer temperatures increase evaporative demand in the atmosphere, and thus (assuming sufficient soil moisture is available) increase moisture loss from evapotranspiration (*high confidence*) (Dai et al., 2018; Vicente-Serrano et al., 2020b). On a regional level, aridity is further modulated by seasonal rainfall patterns, runoff, water storage, and interactions with vegetation.

Vegetation is a crucial interface between subsurface water storage (in soil moisture and groundwater) and the atmosphere. Plants alter evapotranspiration and the surface energy balance, and thus can have a large influence on regional aridity (Lemordant et al., 2018). SRCCL concluded there is *high confidence* that higher atmospheric CO_2 increases the ratio of plant CO_2 uptake to water loss (water-use efficiency; WUE) through the combined enhancement of photosynthesis and stomatal regulation (De Kauwe et al., 2013; Jones et al., 2013b; Deryng et al., 2016; Swann et al., 2016; Cheng et al., 2017; Knauer et al., 2017; Peters et al., 2018; Guerrieri et al., 2019) (see also Section 5.4.1). Modelling studies suggest that increasing WUE can partly counteract water losses from increased evaporative demand in a warmer atmosphere, potentially mitigating aridification (Milly and Dunne, 2016; Bonfils et al., 2017; Cook et al., 2018; Yang et al., 2018d). However, observational studies suggest that this effect may be counter-balanced by the increase in plant growth in response to elevated CO_2, which results in increased water consumption (De Kauwe et al., 2013; Donohue et al., 2013; Ukkola et al., 2016b; Yang et al., 2016; Guerrieri et al., 2019; Mankin et al., 2019; Singh et al., 2020a). In semi-arid regions, increased plant water consumption can reduce streamflow and exacerbate aridification (Ukkola et al., 2016b; Mankin et al., 2019; Singh et al., 2020a). Thus, there is *low confidence* that increased WUE in plants can counterbalance increased evaporative demand (Cross Chapter Box 5.1).

A drought is a period of abnormally dry weather that persists for long enough to cause a serious hydrological imbalance (Wilhite and Glantz, 1985; Wilhite, 2000; Cook et al., 2018) (see Annex VII: Glossary). Most droughts begin as persistent precipitation deficits (*meteorological drought*) that propagate over time into deficits in soil moisture, streamflow, and water storage (Figure 8.6), leading to a reduction in water supply (*hydrological drought*). Increased atmospheric evaporative demand increases plant water stress, leading to *agricultural and ecological drought* (Williams et al., 2013; Allen et al., 2015a; Anderegg et al., 2016; McDowell et al., 2016; Grossiord et al., 2020). Evaporative demand affects plants in two ways. It increases evapotranspiration, depleting soil moisture and stressing plants through lack of water (Teuling et al., 2013; Sperry et al., 2016), and also directly affects plant physiology, causing a decline in hydraulic conductance and carbon metabolism, leading to mortality (Breshears et al., 2013; Hartmann, 2015; McDowell and Allen, 2015; Fontes et al., 2018) (Figure 8.6). While droughts are traditionally viewed as “slow moving" disasters that typically take months or years to develop, rapidly evolving and often unpredictable *flash droughts* can also occur (Otkin et al., 2016, 2018). *Flash droughts* can develop within a few weeks, causing substantial disruption to agriculture and water resources (Pendergrass et al., 2020). Conversely, droughts that persist for a long time (usually a decade or more) are called *megadroughts*. Droughts span a large range of spatial and temporal scales, arise through a variety of climate system dynamics (e.g., internal atmospheric variability, ocean teleconnections), and can be amplified or alleviated by a variety of physical and biological processes. As such, droughts occupy a unique space within the framework of extreme climate and weather events, possessing no singular definition.

While the role of precipitation in droughts is obvious, other climatic drivers are also important, such as temperature, radiation, wind, and humidity (Figure 8.6). These factors have a strong influence on atmospheric evaporative demand, which affects evapotranspiration and soil moisture (Figure 8.6). In snow-dominated regions, high temperatures increase the fraction of precipitation falling as rain instead of snow and advance the timing of spring snowmelt (*high confidence*) (Vincent et al., 2015; Mote et al., 2016, 2018; Berg and Hall, 2017; Solander et al., 2018). This can result in lower than normal snowpack levels (*a snow drought*), and thus reduced streamflow, even if total precipitation is at or above normal for the cold season (Harpold et al., 2017). Plants also affect the severity of droughts by modulating evapotranspiration (Figure 8.6). As discussed above, the effect of elevated CO_2 on plants has the potential to both increase and reduce water loss through evapotranspiration via enhanced WUE and plant growth, respectively (Figure 8.6), but

ACCEPTED VERSION SUBJECT TO FINAL EDITING

there is *low confidence* in whether one process dominates over another at the global scale.

Drought severity also depends on human activities and decision-making (AghaKouchak et al., 2015; Van Loon et al., 2016; Pendergrass et al., 2020). Societies have developed a variety of strategies to manipulate the water cycle to increase resiliency in the face of water scarcity, including irrigation, creation of artificial reservoirs, and groundwater pumping. While potentially buffering water resource capacity, in some cases these interventions may unexpectedly increase vulnerability (*medium confidence*). For example, while increased irrigation efficiency may ensure more water is available to crops, the corresponding reduction in runoff and subsurface recharge may exacerbate hydrologic drought (Grafton et al., 2018). Furthermore, while building dams and increasing surface reservoir capacity can boost water resources, they may actually increase drought vulnerability if demands rise to take advantage of the increased supply or if over-reliance on these surface reservoirs is encouraged (Di Baldassarre et al., 2018). Interactions between adaptation, vulnerability, and drought impacts are discussed further in WGII (Chapters 2 and 4).

In summary, there is *high confidence* that a warming climate drives an increase in atmospheric evaporative demand, decreasing available soil moisture. There is *high confidence* that higher atmospheric CO_2 increases plant water-use efficiency, but *low confidence* that this physiological effect can counterbalance water losses. Since drought can be defined in a number of ways, there are potentially different responses under a warming climate depending on drought type. Beyond a lack of precipitation, changes in evapotranspiration are critical components of drought, because these can lead to soil moisture declines (*high confidence*). Under very dry soil conditions, evapotranspiration becomes restricted and plants experience water stress in response to increased atmospheric demand (*medium confidence*). Human activities and decision-making have a critical impact on drought severity (*high confidence*).

[START FIGURE 8.6 HERE]

Figure 8.6: Climatic drivers of drought, effects on water availability, and impacts. Plus and minus signs denote the direction of change that drivers have on factors such as snowpack, evapotranspiration, soil moisture, and water storage. The three main types of drought are listed, along with some possible environmental and socioeconomic impacts of drought (bottom).

[END FIGURE 8.6 HERE]

8.2.3.4 Direct anthropogenic influence on the regional water cycle

Human activities influence the regional water cycle directly through modifying and exploiting stores and flows from rivers, lakes and ground water and by altering land cover characteristics. These actions alter surface energy and water balances through changes in permeability, surface albedo, evapotranspiration, surface roughness and leaf area. Direct redistribution of water by human activities for domestic, agricultural and industrial use of ~24,000 km^3 per year (Figure 8.1) is equivalent to half the global river discharge or double the global groundwater recharge each year (Abbott et al., 2019). Since the AR5, both modelling studies and observations have demonstrated that land use change can drive local and remote responses in precipitation and river flow by altering the surface energy balance, moisture advection and recycling, land-sea thermal contrast and associated wind patterns (Alter et al., 2015; Wey et al., 2015; De Vrese et al., 2016; Pei et al., 2016; Wang-Erlandsson et al., 2018; Vicente-Serrano et al., 2019). There is robust evidence that a warming climate combined with direct human demand for ground water will deplete ground water resources in already dry regions (Wada and Bierkens, 2014; D'Odorico et al., 2018; Jia et al., 2020).

SRCCL presented evidence that extraction of water from the ground or river systems and intensive irrigation increases evaporation and atmospheric water vapour locally (Jia et al., 2020; Mishra et al., 2020). Irrigation can explain declining groundwater storage in some regions, including north-western India and North America (Asoka et al., 2017; Ferguson et al., 2018b). Simulations spanning 1960-2010 indicate that ~30% of the present human water consumption is supplied from non-sustainable water resources (Wada and Bierkens,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2014). However, there is only limited evidence that groundwater extraction is lowering streamflow (Mukherjee et al., 2018; de Graaf et al., 2019). Model experiments show that irrigation can either aggravate or alleviate climate-induced changes of surface or sub-surface water (Leng et al., 2015). Widespread extraction of water from rivers can reduce flows and decrease the level and area of inland seas and lakes (Wurtsbaugh et al., 2017; Torres-Batlló et al., 2020; Wang et al., 2020d). Between 1985 and 2015, ~139,000 km^2 of inland water areas have become land, while creation of dams has converted about 95,000 km^2 of land to water, particularly in the Amazon and Tibetan Plateau (Donchyts et al., 2016). Direct management of river flow is comparable in magnitude to climate change effects for snow-fed rivers at a continental scale based on a global analysis and a study of 96 Canadian catchments (Tan and Gan, 2015; Arheimer et al., 2017).

SRCCL assessed with *medium confidence* that mean and extreme precipitation is increased over and downwind of urban areas (Jia et al., 2020). There is *medium confidence* that altered thermodynamic and aerodynamic properties of the land surface from urbanisation affects evaporation and increases precipitation over or downwind of cities (Box 10.3) due to altered stability and turbulence (Han et al., 2014; Pathirana et al., 2014; Jiang et al., 2016; D'Odorico et al., 2018; Sarangi et al., 2018; Boyaj et al., 2020), while reduced biogenic aerosol but increased anthropogenic aerosol emissions modify cloud microphysics and precipitation processes (Schmid and Niyogi, 2017; D'Odorico et al., 2018; Fan et al., 2020; Zheng et al., 2020)(Box 8.1). Urbanisation also decreases permeability of the surface, leading to increased surface runoff (Chen et al., 2017; Jia et al., 2020). Large-scale infrastructure, such as the construction and operation of dikes, weirs, and hydropower plants, also alters surface energy and moisture fluxes, potentially influencing the regional water cycle. *Limited* modelling *evidence* suggests that large-scale solar and wind farms can increase precipitation locally (over the Sahel and North America) when dynamic vegetation responses are represented (Li et al., 2018c; Pryor et al., 2020) with remote effects also possible (Lu et al., 2021).

Changes in land use from forest to agriculture can exert profound regional effects on the water cycle (FAQ 8.1) by modifying the surface energy balance and moisture recycling (Krishnan et al., 2016; Paul et al., 2016; Llopart et al., 2018; Singh et al., 2019). There is *medium evidence* from modelling and observations over the Amazon and East Africa that deforestation drives increased streamflow (Dos Santos et al., 2018; Guzha et al., 2018; Levy et al., 2018) but *limited evidence* that increases in global runoff due to deforestation are counterbalanced by decreases resulting from irrigation (Hoegh-Guldberg et al., 2019). Total Amazon deforestation drives large reductions in precipitation but with a 90% confidence range (-38 to +5%) based on 44 primarily pre-AR5 climate model simulations (Spracklen and Garcia-Carreras, 2015) with smaller reductions (-2.3 to -1.3%) attributed to observed Amazon deforestation up to 2010. Climate model development has reduced this uncertainty range but has not altered the median change (Lejeune et al., 2015). Large-scale global deforestation (20 million km^2) simulated by 9 CMIP6 models confirms a large range in precipitation amount reduction of -37±54 mm/yr over the deforested regions (Boysen et al., 2020). However, small-scale deforestation can increase precipitation locally (Lawrence and Vandecar, 2015). A 50–60% deforestation rate corresponded to a wet season delay of about one week and greater chance of dry spells of eight days or longer based on correlation analysis of rain gauge and land use data for South America (Leite-Filho et al., 2019). Forest and grassland fires can also modify hydrological response at the watershed scale (Havel et al., 2018). Afforestation or reforestation aimed at removing CO_2 from the atmosphere can also alter the water cycle at the regional scale (Section 8.4.3 and Cross-Chapter Box 5.1).

In summary, there is *high confidence* that land use change and water extraction for irrigation drive local, regional and remote responses in the water cycle. Large-scale deforestation is *likely* to decrease precipitation over the deforested regions but there is *low confidence* in the effects of limited deforestation. There is *medium confidence* that deforestation drives increased streamflow relative to the responses caused by climate change. There is *medium confidence* that urbanisation can increase local precipitation and runoff intensity. A warming climate combined with direct human demand for water is expected to deplete ground water resources in dry regions (*high confidence*).

[START BOX 8.1 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

BOX 8.1: Role of anthropogenic aerosols in water cycle changes

Aerosols affect precipitation in two major pathways, by altering the shortwave and longwave radiation and influencing cloud microphysical properties.

Aerosol radiative effects on precipitation

Aerosols scatter and absorb solar radiation which reduces the energy available for surface evaporation and subsequent precipitation. In addition, cooling is incurred by the radiation that is reflected back to space directly by the aerosols and indirectly by the aerosol effect on cloud brightening. Northern Hemisphere (NH) station data indicate decreasing precipitation trends during 1950s-1980s, which have since partially recovered (Wild, 2012; Bonfils et al., 2020). These changes are attributable with *high confidence* to anthropogenic aerosol emissions from North America and Europe causing dimming through reduced surface solar radiation, which peaked during the late-1970s and partially recovered thereafter following improved air quality regulations (Section 6.2.1; Box 8.1, Figure 1).

[START BOX 8.1, FIGURE 1 HERE]

Box 8.1, Figure 1: Northern hemisphere surface downward radiation anomalies (Wm^{-2} ; a) and precipitation anomalies (mm/day ; b) for 1951–2014 for summer season (May–September) monsoon region (Polson et al. et al., 2014a) **from CMIP6 DAMIP experiments**. Observed solar radiation anomalies are from GEBA global data from 1961-2014 (Wild et al., 2017) and observed precipitation anomalies are from GPCC and CRU. CMIP6 multi-model mean anomalies are from all-forcings (ALL), greenhouse gas forcing (GHG) and anthropogenic aerosol forcing (AER) experiments. Anomalies are with respect to 1961–1990 and smoothed with a 11-year running mean. Red shading shows the ensemble spread of ALL forcing experiment (5%–95% range). Models are masked to the GPCC data set. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END BOX 8.1, FIGURE 1 HERE]

Dimming over the NH causes a relative cooling, compared to the SH, which induces a southward shift of the northern edge of the tropical rain belt (Allen et al., 2014; Brönnimann et al., 2015) (Section 3.3.2.2). CMIP5 simulations show that most of the cooling is caused by the aerosol cloud-mediated effect (Chung and Soden, 2017). Dimming also weakens monsoon flow and precipitation, offsetting or even overcoming the expected precipitation increase due to increased GHGs (Ayantika et al et al., 2021). The oceanic response to a weakened monsoon cross-equatorial flow can further weaken the South Asian monsoon through an amplifying feedback loop (Swapna et al., 2012; Krishnan et al., 2016; Patil et al., 2019) These processes partially explain (*medium confidence*) the southward shift of the NH tropical edge of the tropical rain belt from the 1950s to the 1980s (Allen et al., 2014; Brönnimann et al., 2015) and the severe drought in the Sahel that peaked in the mid-1980s (Rotstayn et al., 2002; Undorf et al., 2018). These processes also explain (*high confidence*) the observed decrease of southeast Asian Monsoon precipitation during the second half of the 20th century (Bollasina et al. et al., 2011; Sanap et al., 2015; Krishnan et al., 2016; Lau and Kim, 2017; Lin et al., 2018; Undorf et al., 2018) (Figure 8.7).

Absorption of solar radiation by anthropogenic aerosols such as black carbon warms the lower troposphere and increases moist static energy but also results in larger convection inhibition that suppresses light rainfall (Wang et al., 2013c) (Box 8.1, Figure 2). Release of aerosol-induced instability, often triggered by topographical barriers, produces intense rainfall, flooding (Fan et al., 2015; Lee et al., 2016) and severe convective storms (Saide et al., 2015) (*medium confidence*). In particular, aerosols induce intense convection at the Himalaya foothills during the pre-monsoon season, which generates a regional convergence there (*medium confidence).* This mechanism is termed the "elevated heat pump hypothesis" (Lau and Kim, 2006; D'Errico et al., 2015).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[START BOX 8.1, FIGURE 2 HERE]

Box 8.1, Figure 2: Schematic depiction of the atmospheric effects of light absorbing aerosols on convection and cloud formation: (A) without and (B) with the presence of absorbing aerosols in the planetary boundary layer. The dashed and solid blue lines correspond to the vertical temperature profiles in the absence and presence of the absorbing aerosol layer, respectively, and the solid and dashed red lines denote the dry and moist adiabats, respectively. Absorbing aerosols result in an increasing temperature in the atmosphere but a reduced temperature at the surface. The reduced surface temperature and the increased temperature aloft lead to a larger negative energy associated with convective inhibition (-) and a higher convection condensation level (CCL) under the polluted conditions. On the other hand, the absorbing aerosol layer induces a larger convective available potential energy (+) above CCL, facilitating more intensive vertical development of clouds, if lifting is sufficient to overcome the larger convective inhibition. From (Wang et al., 2013).

[END BOX 8.1, FIGURE 2 HERE]

Aerosol cloud microphysical effects

Cloud droplets nucleate on pre-existing aerosol particles which act as cloud condensation nuclei (CCN). Anthropogenic aerosols add CCN, compared to a pristine background, and produce clouds with more numerous and smaller droplets, slower to coalesce into raindrops and to freeze into ice hydrometeors at temperatures below 0°C. Adding CCN suppresses light rainfall from shallow and short-lived clouds, but it is compensated by heavier rainfall from deep clouds. Adding aerosols to clouds in extremely clean air invigorates them by more efficient vapour condensation on the added drop surfaces (Koren et al., 2014; Fan et al., 2018). Clouds forming in more polluted air masses (hence with more numerous and smaller drops) need to grow deeper to initiate rain (Freud and Rosenfeld, 2012; Konwar et al., 2012; Campos Braga et al., 2017). This leads to larger amount of cloud water evaporating aloft while cooling and moistening the air there at the expense of the lower levels, which leads to convective invigoration (Dagan et al., 2017; Chua and Ming, 2020), followed by convergence, air mass destabilization and added rainfall in an amplifying feedback loop (Abbott and Cronin, 2021). In addition, delaying rain initiation until greater altitudes are reached transports more cloud water above the 0°C altitude and leads to additional release of latent heat of freezing and/or vapour deposition, which in combination with the added latent heat of condensation enhances the cloud updrafts (Fan et al., 2018). The stronger updrafts invigorate mixed phase precipitation and the resultant hail and cloud electrification (Rosenfeld et al., 2008a; Thornton et al., 2017). This includes the outer convective rainbands of tropical cyclones and there is *medium confidence* that air pollution enhances flood hazard associated with the outer rain bands at the expense of the inner rain bands (Wang et al., 2014; Zhao et al., 2018a; Souri et al., 2020).

The aerosol effect on invigoration and rainfall from deep convective clouds peaks at moderate levels (aerosol optical depth of 0.2 to 0.3), but reverses into suppression with more aerosols (Liu et al., 2019a). More generally, the microphysical aerosol-related processes often compensate or buffer each other (Stevens and Feingold, 2009). For example, suppressed rain by slowing drop coalescence enhances mixed phase precipitation. Therefore, despite the potentially large aerosol influence on the precipitation forming processes, the net outcome of aerosol microphysical effects on precipitation amount has generally *low confidence*, especially when evaluated with respect to the background of high natural variability in precipitation (Tao et al., 2012).

Ice nucleating particles (INP) aerosols initiate ice precipitation from persistent supercooled water clouds that have cloud droplets too small for efficient warm rain, or expedite mixed phase precipitation in short lived supercooled rain clouds (Creamean et al., 2013). Most INP are desert and soil dust particles, rather than air pollution aerosols (DeMott et al., 2010). Biogenic particles from terrestrial and marine origin are more rare, but important at temperatures above about -15°C (Murray et al., 2012; DeMott et al., 2016). Dust particles from long-range transport across the Pacific were found to enhance snow forming processes over the Sierra Nevada in California (Creamean et al., 2013; Fan et al., 2014). The impact of INP was demonstrated by

ACCEPTED VERSION SUBJECT TO FINAL EDITING

glaciogenic cloud seeding experiments, which enhanced orographic supercooled clouds with *medium confidence* of success (French et al., 2018; Rauber et al., 2019; Friedrich et al., 2020). There are still major gaps in understanding the effects of INP mainly on deep convective clouds (Kanji et al., 2017; Stanford et al., 2017; Korolev et al., 2020)

[END BOX 8.1 HERE]

8.3 How is the water cycle changing and why?

This section focuses on the evaluation and attribution of past and recent water cycle changes using observational datasets, theoretical understanding and model simulations. Paleoclimate records and historical observations provide evidence for past water cycle changes caused both by natural variability and human activities (Haug et al., 2003; Buckley et al., 2010; Pederson et al., 2014). Key elements of the observed water cycle changes are assessed in this section, including flux and storage variations across the atmosphere, the continents and to a lesser extent the ocean and cryosphere, as well as related changes in large-scale atmospheric circulation and modes of variability. Particular emphasis is placed on assessing changes across regions and seasons (Box 8.2). Detailed regional assessments are presented in Chapters 10, 11, 12 and Atlas. Further information concerning large-scale observed water cycle changes and their attribution is available in Sections 2.3.1.3 and 3.3.2.

8.3.1 Observed water cycle changes based on multiple datasets

This section provides a process-based evaluation and a comprehensive assessment of observed water cycle changes by integrating multiple lines of evidence including paleoclimate data, historical datasets, theoretical understanding (Section 8.2) and model simulations.

8.3.1.1 Global water cycle intensity and P-E over land and oceans

The human influence on the global water cycle is often summarized as an intensification (Huntington, 2006; DeAngelis et al., 2015; Zhang et al., 2019c) or an overall strengthening which has been observed since at least 1980 (*high confidence*, see Chapter 2). There is however no unique definition of the global water cycle intensity (Trenberth, 2011; Ficklin et al., 2019; Sprenger et al., 2019). One simple metric is the global and annual mean amount of precipitation. Although an increase in global precipitation is consistent with physical expectations (Section 8.2.1), it has not yet been detected and attributed to human activities given large observational uncertainties and low signal-to-noise ratio (Section 8.3.3.2). Other metrics are more suitable to detect and attribute changes in the global water cycle, including the *likely* increase in global land precipitation since 1950 (Section 2.3.1.4) which is *likely* due to a human influence (Section 3.3.2.2).

The flux of fresh water between the ocean and atmosphere is determined by the difference between precipitation and evaporation (P-E). Evaporation is measured in very few locations across the global ocean, so that directly assessing P-E over the ocean is very challenging and relies on indirect reanalysis estimates (Robertson et al., 2020). AR5 presented *robust evidence* of an amplified oceanic pattern in P-E since the 1960s from both regional and global surface and subsurface salinity measurements and reanalyses. This pattern is consistent with our theoretical understanding of human induced changes in the water cycle, leading to the conclusion that these changes are *very likely* the result of anthropogenic forcings (Section 9.2.2.2).

In contrast, AR5 did not provide a conclusive assessment of observed changes in P-E over land. Continental P-E estimated from reanalyses and data-driven land-surface models indicate that interannual variations are linked to ENSO (Robertson et al., 2014, 2020). Increasing trends in P-E since 1979 based on land models are not statistically significant. Observations and models show evidence that P-E increases in the wet parts and decreases in the dry parts of tropical circulation systems, which shift in location seasonally and from year to year, with increases in seasonality since 1979 (Chou et al., 2013; Liu and Allan, 2013; Fu and Feng, 2014,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

see also Box 8.2).

In summary, a low signal-to-noise ratio, observational uncertainties and current data assimilation techniques limit the assessment of recent global trends in P-E over both land and ocean. It is *likely* that the global land P-E variations observed since the late 1970s were dominated by internal variability, mostly linked to ENSO teleconnections (*medium confidence*). In contrast, the attribution of changes in sea surface salinity (Section 3.5.2.2) suggests that it is *extremely likely* that human influence has contributed to the regional changes in P-E observed over the global ocean since the mid-20th century.

8.3.1.2 Water vapour and its transport

AR5 presented evidence of increases in global near-surface and tropospheric specific humidity since the 1970s but with *medium confidence* of a slowing of near-surface moistening trends over land associated with reduced relative humidity since the late 1990s. According to the AR5, radiosonde, Global Positioning System (GPS) and satellite observations of tropospheric water vapour indicate *very likely* increases at near global scales since the 1970s occurring at a rate that is generally consistent with the Clausius-Clapeyron relation (about 7% per ºC at low altitudes) and the observed atmospheric warming (Hartmann et al., 2013).

Since AR5, it is *very likely* that increases in global atmospheric water vapour are observed from in situ, satellite and reanalysis data (with *medium confidence* in the magnitude; Section 2.3.1.3). Satellite records show increases in upper tropospheric water vapour (constant relative humidity while temperatures have increased) since 1979 (Chung et al., 2014b; Blunden and Arndt, 2020), to which human influence has *likely* contributed (Section 3.3.2.1). Combined satellite and reanalysis estimates and CMIP6 atmosphere-only simulations (1988–2014) show global-mean precipitable water vapour increases of 6.7±0.3%/°C, very close to the Clausius Clapeyron rate (Allan et al., 2020). Satellite-based products show increases close to the Clausius-Clapeyron rate over the ice-free oceans (about 7 to 9 %/ºC; 1998-2008), but reanalysis estimates outside this range (Schröder et al., 2019) are an expected consequence of their changing observing systems (Allan et al., 2014; Parracho et al., 2018). Increases in precipitable water vapour are found over the central and sub-Arctic based on multiple reanalyses with some corroboration from sparse, in situ data (Vihma et al., 2016; Rinke et al., 2019; Nygård et al., 2020).

Declining near-surface relative humidity over land areas (e.g., United States, Mediterranean, south Asia, South America and southern Africa) is evident in surface observations (Willett et al., 2014, 2020; Dunn et al., 2017). This is consistent with a faster rate of warming over land than ocean (Byrne and O'Gorman, 2018) (see Sections 2.3.1.3 and 8.2.2.1). CMIP5 simulations underestimate the observed decreases in relative humidity over much of global land during 1979-2015 (Douville and Plazzotta, 2017; Dunn et al., 2017) even when observed SSTs are prescribed (-0.05 to -0.25 %/decade compared with an observed rate of -0.4 to -0.8 %/decade). It is not yet clear if this discrepancy is related to internal variability or can be explained by deficiencies in models (Vannière et al., 2019; Douville et al., 2020) or observations (Willett et al., 2014). Over the Northern Hemisphere mid-latitude continents, there is *medium confidence* that human influence has contributed to a decrease in near-surface relative humidity in summer (Sections 2.3.1.3 and 3.3.2.2).

Water vapour transport (or convergence) estimates from observations have substantial uncertainties even in regions of high quality radiosonde data. Consequently many studies use reanalyses for water transport estimates instead of instrumental observations. For example, increases in low-level (800-1000 hPa) moisture convergence into the tropical wet regime with a smaller outflow increase in the mid-troposphere (400-800 hPa) with warming was detected in one reanalysis (ERA-Interim) (Allan et al., 2014). Modelling evidence combined with statistical analysis demonstrate consistency between reanalysis moisture convergence and P-E over land (Robertson et al., 2016). Advances in reanalysis representation of atmospheric moisture and winds in addition to new observational isotope analysis have improved the ability to identify the main sources of water vapour for key continental regions and quantify the relative contributions from moisture advection and recycling (Gimeno et al., 2012; Van Der Ent et al., 2014; Joseph et al., 2016).

Observed changes in moisture transport can also arise from changes in atmospheric circulation as well as

ACCEPTED VERSION SUBJECT TO FINAL EDITING

thermodynamics. For instance, moisture transport into the Arctic region estimated from reanalyses datasets is consistent with radiosonde data (Dufour et al., 2016), with increases since 1979 linked to atmospheric circulation (Nygård et al., 2020). Moisture transport into the Eurasian Arctic was identified to increase by 2.6%/decade during 1948-2008 based on a reanalysis estimate (Zhang et al., 2013b). More intense moist intrusions associated with atmospheric rivers affecting the Arctic and Europe have been documented since 1979 but with a substantial influence from decadal internal variability (Ummenhofer et al., 2017; Mattingly et al., 2018). A recent strengthening of tropical circulation and associated moisture convergence has been idendified since around 2000 for the Amazon region (Arias et al., 2015; Barichivich et al., 2018; Espinoza et al., 2018a; Wang et al., 2018e). This was also strenghtened by increased moisture transport from the North Atlantic, driving more abundant latent heat release (Segura et al., 2020) and leading to an increased frequency of extreme floods in the northern Amazon (Barichivich et al., 2018; Heerspink et al., 2020). Overall, increased moisture transport has been linked to increased precipitation over wet tropical land areas (Gimeno et al., 2020) and to more extreme and persistent wet and dry weather events (Konapala et al., 2020) in many regions worldwide.

In summary, there is *high confidence* that human-caused global warming has led to an overall increase in water vapour and moisture transport throughout the troposphere, at least since the mid-1990s. In particular, there is *high confidence* that moisture transport into the Arctic has increased but only *medium confidence* in the attribution of such a trend to a human influence. There is *medium confidence* that human influence has contributed to a decrease in near-surface relative humidity over the Northern Hemisphere mid-latitude continents during summer (see also Sections 2.3.1.3 and 3.3.2.2).

8.3.1.3 Precipitation amount, frequency and intensity

This section assesses observed changes in precipitation at global and regional scales. Note that changes in precipitation seasonality are assessed in Box 8.2 and that changes in regional monsoons are assessed in section 8.3.2.4 where observed changes in both circulation and rainfall are considered. Further assessment of regional changes in precipitation is presented in Chapters 10, 12 and Atlas, while extreme precipitation is presented in Chapter 11.

AR5 concluded that it is *likely* there has been an overall increase in annual mean precipitation amount over mid-latitude land areas in the Northern Hemisphere, with *low confidence* since 1901, but *medium confidence* after 1951. There is further evidence of a faster increase since the 1980s (*medium confidence*) (Sections 2.3.1.3.4 and 3.3.2.1). Precipitation has increased from 1950 to 2018 over mid-high latitude Eurasia, most North America, southeastern South America, and northwestern Australia, while it has decreased over most of Africa, eastern Australia, the Mediterranean region, the Middle East, and parts of East Asia, central South America, and the Pacific coasts of Canada, as simulated by the CMIP5 multi-ensemble mean (Dai, 2021). Since AR5, there have been updates of several precipitation datasets, including satellite estimates, reanalysis and merged products (Adler et al., 2017; Roca, 2019). However, observational uncertainties remain an issue for assessing regional trends in seasonal or annual mean precipitation amount (Hegerl et al., 2015; Maidment et al., 2015; Sarojini et al., 2016), as well as the convective and stratiform types of precipitation (e.g., Ye et al., 2017). Precipitation trends at regional scales are dominated by internal variability across much of the world (Knutson and Zeng et al., 2018). Regional changes in precipitation amounts can also be obscured by contrasting responses to GHG versus aerosol forcings (Wu et al., 2013; Hegerl et al., 2015; Xie et al., 2016; Zhao and Suzuki, 2019; Zhao et al., 2020) and changes in precipitation intensity versus frequency (Shang et al., 2019).

Global and regional changes in precipitation frequency and intensity have been observed over recent decades. An analysis of 1875 rain gauge records worldwide over the period 1961–2018 indicates that there has been a general increase in the probability of precipitation exceeding 50 mm/day, mostly due to an overall boost in rain intensity (Benestad et al., 2019). Such changes in precipitation intensity and frequency have not been formally attributed to human activities, but are consistent with the heating effect of increasing CO_2 levels on the distribution of daily precipitation rates (Section 8.2.3.2) and with a distinct overall intensification of heavy precipitation events found in both observations and CMIP5 models, though with an

ACCEPTED VERSION SUBJECT TO FINAL EDITING

underestimated magnitude (Fischer and Knutti, 2014). Beyond amplified precipitation extremes (Section 11.4.2), CMIP5 models also indicate that anthropogenic forcings have increased temporal variability of annual precipitation amount over land from 1950 to 2005, which is most pronounced in annual mean daily precipitation intensity (Konapala et al., 2017).

Anthropogenic aerosols can alter precipitation intensities both through radiative and microphysical effects (Box 8.1; Section 8.5.1.1.2). Precipitation suppression through aerosol microphysical effects has been observed in shallow cloud regimes over South America and the southeastern Atlantic, associated with local biomass burning (Andreae et al., 2004; Costantino and Bréon, 2010), and in industrial regions in Australia (Rosenfeld, 2000; Hewson et al., 2013; Heinzeller et al., 2016). In contrast, precipitation intensification through aerosol microphysical effects in deep convective clouds is seen in many regions such as the Amazon, southern United States, India, and Korea associated with anthropogenic aerosols from cities (Hewson et al., 2013; Fan et al., 2018; Lee et al., 2018b; Sarangi et al., 2018).

In the tropics, increases in precipitation amount are observed in convergence zones and decreases in the descending branches of the atmospheric circulation since 1979 (Chou et al., 2013; Liu and Allan, 2013; Gu et al., 2016; Polson et al., 2016; Polson and Hegerl, 2017), consistent with increased moisture transports with warming (Gimeno et al., 2020). Over tropical land areas, there is substantial variability in the "wet convergent regimes get wetter" and "dry divergent regimes get drier" pattern of trends observed since 1950 that are modulated by decadal changes in ENSO (Liu and Allan, 2013; Gu and Adler, 2018). CMIP6 models indicate an increased contrast between wet and dry regions in the tropics and subtropics (Schurer et al., 2020) (Figure 8.7). This provides further evidence that rainfall has increased in wet regimes, and slightly decreased in dry regimes over the period 1988-2019 (Figure 3.14). This greater contrast is primarily attributable to greenhouse gas forcings, although the observed trends are statistically larger than the model responses (Section 3.3.2.2).

Over the African continent, there are distinct precipitation trends observed in multiple datasets since the 1980s (Maidment et al., 2015; Nguyen et al., 2018b) (Figure 8.7). Increases in intense convective storms affecting the Sahel have been attributed to increased land-ocean temperature gradients (Taylor et al., 2017), enhanced by intense heating of the Sahara (Dong and Sutton, 2015) rather than thermodynamics (Section 8.2.2). Changes in Sahel rainfall, with reduced precipitation amounts from the 1960s to the 1980s and a subsequent recovery, are assessed in Section 8.3.2.4.3 and Section 10.4.2.1. In eastern Africa, decreasing precipitation amount (−2 to −7% per decade for 1983-2010) was reported for the March-to-May Long Rains season (Lyon and Dewitt, 2012; Viste et al., 2013; Liebmann et al., 2014; Maidment et al., 2015; Rowell et al., 2015) and evidence of a recovery since, with internal variability playing a large role in these decadal changes (Wainwright et al., 2019). In contrast, the second "Short Rains" season in Eastern Africa (October to December) does not exhibit significant precipitation trends (Rowell et al., 2015). Increases in annual southern Africa rainfall of 6-7% per decade during 1983-2010 are linked with the Pacific Decadal Oscillation (PDO) (Maidment et al., 2015).

Section 8.3.1.6 assesses changes in precipitation over the Mediterranean region and its connection with drought and aridity.

Rainfall increases have been observed over northern Australia since the 1950s, with most of the increases occurring in the north-west (Dey et al., 2018, 2019b; Dai, 2021) and decreases observed in the north-east (Li et al., 2012a) since the 1970s. In contrast, there has been a decline in rainfall over southern Australia related to changes in the intensification and position of the subtropical ridge (CSIRO and Bureau of Meteorology, 2015) and anthropogenic effects (Knutson and Zeng et al., 2018). The drying trend over southwest Australia is most pronounced during May–July, where rainfall has declined by 20% below the 1900–1969 average since 1970 and by about 28% since 2000 (Bureau of Meteorology and CSIRO, 2020).

Over South America, there is observational and paleoclimate evidence of declining precipitation amount during the past 50 years over the Altiplano and central Chile, primarily explained by the PDO but with at least 25% of the decline attributed to anthropogenic influence (Morales et al., 2012; Neukom et al., 2015; Boisier et al., 2016; Seager et al., 2019b; Garreaud et al., 2020). In contrast, a significant rainfall increase has

ACCEPTED VERSION SUBJECT TO FINAL EDITING

been detected over the Peruvian-Bolivian Altiplano (from observational data and satellite-based estimations) since the 1980s (Imfeld et al., 2020; Segura et al., 2020) (Figure 8.7). Long-term (1902-2005) precipitation data indicate positive trends over southeastern South America and negative trends over the southern Andes, with at least a partial contribution from anthropogenic forcing (Gonzalez et al., 2014; Vera and Díaz, 2015; Díaz and Vera, 2017; Boisier et al., 2018; Knutson and Zeng et al., 2018) (see further assessment in Sections 10.4.2.2 and Atlas.7.2.2). The Peruvian Amazon has exhibited significant rainfall decreases during the dry season since 1980 (Lavado et al., 2013; Ronchail et al., 2018). Increases in wet season rainfall in the northern and central Amazon since the 1980s and decreases during the dry season in the southern Amazon (Barreiro et al., 2014; Gloor et al., 2015; Martín-Gómez and Barreiro, 2016; Espinoza et al., 2018a; Wang et al., 2018e; Haghtalab et al., 2020) are not explained by radiative forcing based on CMIP6 experiments (Figure 8.7) and trends are insignificant over longer periods since 1930 (Kumar et al., 2013) or more recently, since 1973 (Almeida et al., 2017) (see Section 8.3.2.4.5 for monsoon-related changes). For the tropical Andes region, trends in annual precipitation show heterogenous patterns, ranging between -4%/decade and +4%/decade in the north and south tropical Andes for a 30-year period at the end of the 20th century, although increases during 1965-1984 and decreases since 1984 have been registered in Bolivia (Carmona and Poveda, 2014; Pabón-Caicedo et al., 2020).

Over China, annual precipitation totals changed little from 1973 to 2016, but precipitation intensity significantly increased at a rate of 0.12 mm/day/decade, while the number of days with precipitation exceeding 0.1 mm/day significantly decreased at a rate of 0.9 days/decade (Shang et al., 2019). There is consistency in trend estimates during 1998-2015 over mainland China among satellite-based products and station data, which show increased precipitation amounts in autumn and winter and decreases in summer (Chen and Gao, 2018), consistent with a decreased intensity of East-Asian monsoon precipitation (Lin et al., 2014; Deng et al., 2018). Further assessment of precipitation changes over the South and Southeast Asian and the East Asian monsoon regions is presented in Section 8.3.2.4. An increasing trend in the frequency of heavy rainfall occurrences at the expense of low and moderate rainfall occurrences is found over central India (Krishnan et al., 2016; Roxy et al., 2017) and over eastern China with the latter due to increasing high aerosol levels (Qian et al., 2009; Guo et al., 2017a; Xu et al., 2017; Day et al., 2018), consistent with the effects of absorbing aerosol on stability and convective inhibition (Box 8.1).

Observed precipitation records since the early 1900s show increases in precipitation totals over central and northeastern North America that are attributable to anthropogenic warming but larger in magnitude than found in CMIP5 simulations (Knutson and Zeng et al., 2018; Guo et al., 2019). Decreases in precipitation amount over the central and southwestern United States and increases over the north-central United States during 1983-2015 (Cui et al., 2017; Nguyen et al., 2018b), are not clearly associated with forced responses in CMIP6 simulations (Figure 8.7; see also Section 10.4.2.3). Over Europe, precipitation trends since 1979 do not show coherence across datasets (Zolina et al., 2014; Nguyen et al., 2018b). Longer records since 1910 show increases for much of Scandinavia, northwestern Russia, and parts of northwestern Europe/UK and Iceland (Knutson and Zeng et al., 2018). Records since 1930 show increases of annual preciptation amount over western Russia (see also Section Atlas.8.2). Widespread increases in daily precipitation intensity appear clearly over regions with a high density of rain gauges, such as Europe and North America over the 1951-2014 period (Alexander, 2016). Observations during 1966-2016 over northern Eurasia show increases in the contribution of heavy convective showers to total precipitation by 1-2% on average (with local trends of up to 5%) for all seasons except for winter (Chernokulsky et al., 2019). Increases in convective precipitation intensity have been identified, particularly on sub-daily time-scales, using a range of modelling and observational data (Berg et al., 2013; Kanemaru et al., 2017; Pfahl et al., 2017).

Snowfall is an important component of precipitation in high-latitude and mountain watersheds. Reanalysis data indicate significant reductions in annual mean potential snowfall areas over the Northern Hemisphere land by 0.52 million km^2 per decade, with the largest decline over the Alps, with snow water equivalent reductions of about 20 mm per decade (Tamang et al., 2020). In the Tibetan Plateau, region-wide wintertime snowfall has increased but summer snowfall has decreased during the 1960-2014 period (Deng et al., 2017). State-of-the-art model simulations indicate reduced mean annual snowfall in the Arctic, despite the strong precipitation increase, mainly in summer and autum, when temperatures are close to the melting point (Bintanja and Andry, 2017).

[START FIGURE 8.7 HERE]

Figure 8.7: Linear trends in annual mean precipitation (mm/day per decade) for 1901-1984 (left) and 1985-2014 (right): (a & e) observational dataset, and the CMIP6 multi model ensemble mean historical simulations driven by, (b & f) all radiative forcings, (c & g) GHG only radiative forcings, (d & h) aerosol only radiative forcings experiment. Shade without grey cross correspond to the regions exceeding 10 % significant level. Grey crosses correspond to the regions not reaching the 10% statistical significant level. Nine CMIP6-DAMIP models have been used having at least 3 members. The ensemble mean is weighted per each model on the available and used members. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.7 HERE]

In summary, regional changes in precipitation amounts can be obscured by the contrasting responses to GHG and aerosol forcings across much of the 20th century and can be thus dominated by internal variability at decadal to multi-decadal timescales (*high confidence*). There is however a detectable increase in northern high-latitude annual precipitation over land which has been primarily driven by human-induced global warming (*high confidence*, see also Section 3.3.2). Human influence has strengthened the zonal mean precipitation contrast between the wet tropics and dry subtropics since the 1980s (*medium confidence*), although regional studies suggest a more complex precipitation response to evolving anthropogenic forcings. There is *high confidence* that daily mean precipitation intensities have increased since the mid-20th century in a majority of land regions with available observations and it is *likely* that such an increase is mainly due to GHG forcing (see Section 11.4). Section 8.3.2.4 assesses monsoon precipitation changes in detail.

8.3.1.4 Evapotranspiration

AR5 assessed that there was *medium confidence* that pan evaporation declined in most regions over the last 50 years, yet *medium confidence* that evapotranspiration increased from the early 1980s to the late 1990s. Since AR5, these conflicting observations have been attributed to internal variability and by the fact that evapotranspiration is less sensitive to trends in wind speed and is partly controlled by vegetation greening (Zhang et al., 2015a, 2016d; Zeng et al., 2018c). Observation-based estimates show a robust positive trend in global terrestrial evapotranspiration between the early 1980s and the early 2010s (Miralles et al., 2014b; Zeng et al., 2014, 2018c, Zhang et al., 2015a, 2016d). The rate of increase varies among datasets, with an ensemble mean terrestrial average rate of 7.6 ± 1.3 mm $year^{-1}$ $decade^{-1}$ for 1882–2011 (Zeng et al., 2018b). In addition, a decreasing trend in pan evaporation plateaued or reversed after the mid-1990s (Stephens et al., 2018a) has been reported as due to a shift from a dominant influence of wind speed to a dominant effect of water vapour pressure deficit, which has increased sharply since the 1990s (Yuan et al., 2019). The absence of a trend in evapotranspiration in the decade following 1998 was shown to be at least partly an episodic phenomenon associated with ENSO variability (Miralles et al., 2014b; Zhang et al., 2015a; Martens et al., 2018). Thus, there is *medium confidence* that the apparent pause in the increase in global evapotranspiration from 1998 to 2008 is mostly due to internal variability. In contrast to the AR5, there are now consistent trends in pan evaporation and evapotranspiration at the global scale, given the recent increase in both variables since the mid 1990s (*medium confidence*). Given the growing number of quantitative studies, there is *high confidence* that global terrestrial annual evapotranspiration has increased since the early 1980s.

Since AR5, the predominant contribution of transpiration to the observed trends in terrestrial evapotranspiration has been revisited and confirmed (Good et al., 2015; Wei et al., 2017). Using satellite and ecosystem models, Zhu et al., (2016) found a positive trend in leaf area index during 1982-2009, indicating that greening could contribute to the observed positive trend of evapotranspiration, in line with similar studies that focused on the 1981–2012 (Zhang et al., 2016d) and 1982–2013 (Zhang et al., 2015a) periods. Zeng et al. (2018) determined that the 8% global increase in satellite-observed leaf area index between the 1980s and the 2010s may explain an increase in evapotranspiration of 12.0+/-2.4mm/yr (about 55+/-25% of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the total observed increase). Forzieri et al. (2020) estimated that the recent increase in leaf area index led to 3.66 ± 0.45 W/m^2 in latent heat flux (about 51 ± 6 mm/yr) and that the sensitivity of energy fluxes to leaf area index increased by about 20% over the 1982–2016 period. Overall, there is *medium confidence* that greening has contributed to the global increase in evapotranspiration since the 1980s.

Plant water use efficiency is expected to rise with CO_2 levels (*high confidence*, see Section 8.2.3.3 and Box 5.2), and can in theory counteract rising evapotranspiration in a warmer atmosphere (Section 8.2.3.3). However, observational studies suggest that this may not be the case in some ecosystems. For example, Frank et al. (2015) found that while the Water Use Efficency (WUE) increased in European forests across the 20th century, transpiration also increased due to more plant growth, a lengthened growing season, and increased evaporative demand. Likewise Guerrieri et al. (2019) observed that while WUE and photosynthesis increased in North American forests, stomatal conductance experienced only modest declines that were restricted to moisture-limited forests. Other studies further suggest that in many ecosystems increased WUE will not compensate for increased plant growth, amplifying declines in surface water availability (De Kauwe et al., 2013; Ukkola et al., 2016b; Singh et al., 2020a), while drought conditions can also offset the CO_2 fertilization effect and lead to a decline in WUE (Liu et al., 2020a). There is *low confidence* regarding the impact of plant physiological effects on observed trends in evapotranspiration.

An increasing number of studies have identified signals of attribution in the recent observed trends in evapotranspiration. Douville et al. (2013) found that the post-1960 rise in evapotranspiration in both the mid-latitudes and northern high latitudes was related to anthropogenic radiative forcing. An analysis of CMIP5 simulations suggests that anthropogenic forcing accounts for a large fraction of the global-mean evapotranspiration trend from 1982 to 2010 (Dong and Dai, 2017). Padrón et al., (2020) determined that increases in evapotranspiration were responsible for the majority of the anthropogenic pattern in dry-season water availability that dominates global trends since 1984. These findings are further supported by CMIP6 model results (Fig. 8.8) that show that the recent summertime increase in evapotranspiration in the northern mid-and-high latitudes is due to greenhouse gas forcing and decreasing anthropogenic aerosol emissions over Europe.

In summary, there is *high confidence* that terrestrial evapotranspiration has increased since the 1980s. There is *medium confidence* that this trend is driven by both increasing atmospheric water demand and vegetation greening, and *high confidence* that it can be partly attributed to anthropogenic forcing. There is *low confidence* about the extent to which increases in plant water use efficiency have influenced observed changes in evapotranspiration.

[START FIGURE 8.8 HERE]

Figure 8.8: Linear trends in annual mean evapotranspiration (mm/day per decade) for 1901-1984 (left) and 1985-2014 (right): (a & e) LMIP and observational dataset, and the CMIP6 multi model ensemble mean historical simulations driven by, (b & f) all radiative forcings, (c & g) GHG only radiative forcings, (d & h) aerosol only radiative forcings experiment. Shade without grey cross correspond to the regions exceeding 10 % significant level. Grey crosses correspond to the regions not reaching the 10% statistically significant level. Nine CMIP6-DAMIP models have been used having at least 3 members. The ensemble mean is weighted per each model on the available and used members. GLDAS is not available over the early 20th century so was replaced by a multi-model off-line reconstruction, LMIP, which is consistent with GLDAS over the recent period but may be less reliable over the early 20th century given larger uncertainties in the atmospheric forcings. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END OF FIGURE 8.8 HERE]

8.3.1.5 Runoff, streamflow and flooding

AR5 reported *low confidence* in the assessment of trends in global river discharge during the 20th century.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

This is because many streamflow observations have been impacted by land use and dam construction, and the largest river basins worldwide differ in many characteristics, including geography and morphology. In regions with seasonal snow storage, AR5 WGII assessed that there is *robust evidence* and *high agreement* that warming has led to earlier spring discharge maxima and *robust evidence* of earlier breakup of Arctic river ice, as well as indications that warming has led to increased winter flows and decreased summer flows where streamflows are lower and that the observed increases in extreme precipitation led to greater probability of flooding at regional scales with *medium confidence*. SROCC found *robust evidence* and *high agreement* that discharge due to melting glaciers has already reached its maximum point and has begun declining with smaller glaciers, but only *low confidence* that anthropogenic climate change has already affected the frequency and magnitude of floods at the global scale.

Significant trends in streamflow and continental runoff were observed in 55 out of 200 large river basins during 1948-2012, with an even distribution of increasing and decreasing trends (Dai, 2016) (see also Section 2.3.1.3.6). A global detection and attribution study shows that the simulation of spatially heterogeneous historical trends in streamflow is consistent with observed trends only if anthropogenic forcings are considered (Gudmundsson et al., 2019). Section 3.3.2.3 assesses with *medium confidence* that anthropogenic climate change has altered regional and local streamflows, although a significant trend has not been observed in the global average (Sections 2.3.1.3.6 and 3.3.2.3). Multiple human-induced and natural drivers have been shown to play an important but variable role in observed regional trends of streamflow for several different areas (Fenta et al., 2017; Ficklin et al., 2018; Glas et al., 2019; Vicente-Serrano et al., 2019). For instance, decreasing runoff during the dry season have been observed over the Peruvian Amazon since the 1980s (Lavado et al., 2013; Ronchail et al., 2018). Up to 30–50% of the recent multi-decadal decline in streamflow across the Colorado River Basin can be attributed to anthropogenic warming and its impacts on snow and evapotranspiration (Woodhouse et al., 2016; McCabe et al., 2017; Udall and Overpeck, 2017; Xiao et al., 2018; Milly and Dunne, 2020). In the Upper Missouri River basin, Martin et al. (2020) found that warming temperatures have contributed to streamflow reductions since at least the late 20th century. Cold regions in the Northern Hemisphere have experienced an earlier occurrence of snowmelt floods, an overall increase in water availability and streamflow during winter, and a decrease in water availability and streamflow during the warm season (Aygün et al., 2019).

Some studies have suggested that dam construction and water withdrawals can be the dominant drivers in observed trends in streamflow amount (Wada et al., 2013). Regionally, land use and land cover changes have been identified as important factors for streamflow (Chen et al., 2020a). The impact of surface dimming from aerosol emissions on evaporation was identified as a discernible influence in Northern Hemisphere streamflows (Gedney et al., 2014). While changes in annual mean streamflow present a complicated picture, recent studies of changes in the timing of streamflow in snow-influenced basins continue to support a prominent influence from warming (Kang et al., 2016; Dudley et al., 2017; Kam et al., 2018). Global land runoff variations correlate significantly with ENSO variability (Miralles et al., 2014b; Schubert et al., 2016).

Observed changes in flooding are assessed in detail in Chapter 11 and are summarized as follows. For changes in the magnitude of peak flow, recent studies show strong spatial heterogeneity in the sign, size and significance of trends (Section 11.5.2.1). For changes in the frequency and magnitude of high flows, the conclusions remain limited by the large influence of water management (Section 11.5.2.2). For changes in timing of peak flows, recent studies further support observed changes in snowmelt-driven rivers (Section 11.5.2.3). Observed changes in runoff and flood magnitude cannot be explained by precipitation changes alone given the possible season- and region-dependent decreases in antecedent soil moisture and snowmelt which can partly offset the increase in precipitation intensity (Sharma et al., 2018), or the expected effect of urbanization and deforestation which can on the contrary amplify the runoff response (Chen et al., 2017; Abbott et al., 2019; Cavalcante et al., 2019). Simulations of mean and extreme river flows are consistent with the observations only when anthropogenic radiative forcing is considered (Gudmundsson and et al., 2021).

In summary, the assessment of observed trends in the magnitude of runoff, streamflow, and flooding remains challenging, due to the spatial heterogeneity of the signal and to multiple drivers. There is however *high confidence* that the amount and seasonality of peak flows have changed in snowmelt-driven rivers due to warming. There is also *high confidence* that land use change, water management and water withdrawals have

ACCEPTED VERSION SUBJECT TO FINAL EDITING

altered the amount, seasonality, and variability of river discharge, especially in small and human-dominated catchments.

8.3.1.6 Aridity and drought

AR5 reported *low confidence* that changes in drought since the mid-20th century could be attributed to human influence, owing to observational uncertainties and difficulties in distinguishing decadal-scale variability from long-term trends. Changes in soil moisture, a metric of aridity, were not assessed thoroughly in AR5. Since AR5, new satellite products, land-surface reanalyses, and land-surface models have been used to document recent changes in soil moisture at the global scale. The science of detection and attribution has also progressed considerably (Trenberth et al., 2015; Easterling et al., 2016; Stott et al., 2016). Attribution efforts have further benefited from the increased use of paleoclimate information, which provides an important constraint on natural variability that is insufficiently sampled by short observational record (Cook et al., 2018; Kageyama et al., 2018).

Several studies have identified a persistent "fingerprint" of anthropogenic forcing in global trends in aridity spanning the last 120 years. Using a combination of tree ring data, CMIP5 model simulations, and reanalysis products, Marvel et al. (2019) determined that the dominant trend in aridity since 1900, characterized by drying in North and Central America and the Mediterranean, is detectable and attributable to external forcing from 1900–1949. This trend weakens from 1950–1975, possibly due to aerosol forcing (Marvel et al., 2019), but then emerges again from 1981 to present, although it is not detectable in the GLEAM nor MERRA-2 soil moisture reanalysis products. Likewise, Bonfils et al., (2020) investigated changes in precipitation, temperature and continental aridity in CMIP5 historical simulations and found that the dominant multivariate fingerprint, an amplification of wet-dry latitudinal patterns and progressive continental aridification, was associated with greenhouse gas emissions (Figure 8.9 a-d), and the second leading fingerprint was associated with anthropogenic aerosols (Figure 8.9 e-h). This study found that the anthropogenic greenhouse gas signal is statistically detectable in reanalyses over the 1950–2014 period (signal-to-noise ratio above 1.96). Gu et al. (2019) found that a global trend in declining soil moisture is detectable in the GLDAS-2 reanalysis product and is attributable to greenhouse gas forcing. Padrón et al. (2020) reconstructed the global patterns of dry season water availability from 1902–2014, and found it *extremely likely* (99% range) that trends in the last three decades of the analysis period could be attributed to anthropogenic forcing, mainly due to increases in evapotranspiration. It is *very likely* (>90% range) that anthropogenic forcing has affected global patterns of soil moisture over the 20th century.

On a regional scale, the robustness of trend attribution for drought and aridity varies widely. Key trends and their attributions are summarized here, while a complete regional assessment of observed trends in drought and aridity is in Chapter 11 (Sections 11.6.2, 12.3.2 and 12.4).

Several studies have analyzed CMIP5 and land surface models and detected a significant summertime drying trend in the Northern Hemisphere across the late 20th century that is attributable to anthropogenic forcings (Mueller and Zhang, 2016; Douville and Plazzotta, 2017). This trend is mainly driven by dryland areas such as the western United States and west-central Asia, where both reanalysis products and satellite data confirm there has been a persistent decline in soil moisture since 1990 (Liu et al., 2019d). In the western United States, snow deficits have *very likely* contributed to recent drying (Mote et al., 2018). Spring snow water equivalent across the Sierra Nevada Mountains reached a record low in 2015 (Margulis et al., 2016; Mote et al., 2016), possibly the lowest of the last five hundred years (Belmecheri et al., 2016). Over the longer California drought (2011–2015) anthropogenic warming alone reduced snowpack levels in the Sierras by 25% (Berg and Hall, 2017). The northwestern United States also experienced snow drought in 2015, despite near-normal levels of total cold season precipitation (Mote et al., 2016; Marlier et al., 2017). There is *high confidence* that anthropogenic warming contributed to these recent snow droughts (Belmecheri et al., 2016; Mote et al., 2016).

In the western United States, anthropogenic warming is amplifying drought and aridity by increasing evaporative demand and water loss to the atmosphere (Weiss et al., 2009; Overpeck, 2013; Cook et al., 2014;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Griffin and Anchukaitis, 2014; Williams et al., 2020). For the California drought between 2012–2014, Griffin and Anchukaitis (2014) used paleoclimate reconstructions to determine that while rainfall deficits were not unprecedented, record-high temperatures drove an exceptional decline in soil moisture relative to the last millennium. Williams et al. (2015) concluded that anthropogenic warming accounted for 8–27% of the these soil moisture deficits. Robeson (2015) estimated that the California drought was a 1-in-10,000 year event. Tree ring reconstructions indicate that prolonged megadroughts have occurred in the western United States throughout the last 1200 years (Cook et al., 2004, 2010, 2015a) forced by internal variability (Coats et al., 2016; Cook et al., 2016b). However, Williams et al. (2020) determined that 2000–2018 drought across the southwestern United States was the second driest 19-year period since 800 CE, and attributed nearly half the magnitude of this event to anthropogenic forcing (see also Section 10.4.2.3). Evidence for human signals in drought can also be found in western North American streamflow records, as noted above in Section 8.3.1.5. There is *high confidence* that anthropogenic forcing has contributed to recent droughts and drying trends in western North America.

Large areas of east-central Asia experienced drying in the early 2000s as a result of warmer temperatures, lower humidity, and declining soil moisture (Wei and Wang, 2013; Li et al., 2017d; Hessl et al., 2018). Paleoclimate data from the Mongolian plateau suggest that this recent central Asian drought exceeds the 900-year return interval, but is not unprecedented in the last 2060 years (Hessl et al., 2018). There is *low confidence* due to *limited evidence* that recent droughts in central Asia can be attributed to anthropogenic forcing.

The Mediterranean region has experienced notable changes in drought and aridity. A number of studies have identified a decline in precipitation since 1960 and attributed this to anthropogenic forcing (Hoerling et al., 2012; Gudmundsson and Seneviratne, 2016; Knutson and Zeng et al., 2018; Seager et al., 2019b). Kelley et al. (2015) showed that climate change caused a three-fold increase in the likelihood of the 2007–2010 meteorological drought in the eastern Mediterranean. However, historical trends in precipitation across the Mediterranean are spatially variable and contain substantial decadal variability, such that an anthropogenic influence may not be detectable in all areas (Zittis, 2018; Vicente-Serrano et al., 2020a). Records of soil moisture provide a clearer signal, indicating that higher temperatures and increased atmospheric demand have played a strong role in driving Mediterranean aridity (Vicente-Serrano et al., 2014). Hydrological modeling suggests that the recent decline in soil moisture in the Mediterranean is unprecedented in the last 250 years (Hanel et al., 2018). Paleoclimate evidence extends this view, additionally indicating that dryness in the Mediterranean is approaching an extreme condition compared to the last millennium (Markonis et al., 2018) and that the 15 year drought in the Levant (1998–2012) has an 89% likelihood of being the driest of the last 900 years (Cook et al., 2016a). Marvel et al. (2019) found that the Mediterranean region contributes strongly to the anthropogenic warming component of the global trend in aridity. There is *high confidence* that anthropogenic forcings are causing increased aridity and drought severity in the Mediterranean region.

Both central and northeastern Africa have experienced a decline in rainfall since about 1980 (Lyon and Dewitt, 2012; Lyon, 2014; Hua et al., 2016; Nicholson, 2017) (*high confidence*). In central Africa, the decline has been attributed to atmospheric responses to Indo-Pacific sea-surface temperature variability (Hua et al., 2018). In northeastern Africa, droughts have become longer and more intense in recent decades, continuing across rainy seasons (Hoell et al., 2017b; Nicholson, 2017), and this trend appears to be unusual in the context of the last 1500 years (Tierney et al., 2015). Knutson and Zeng (2018) attribute decreased annual precipitation over the Sudan to anthropogenic forcing, but other studies argue that the recent trend cannot yet be distinguished from natural variability, at least over parts of this region (Hoell et al., 2017b; Philip et al., 2018). There remains *low confidence* due to *limited evidence* that drying the northeastern Africa is attributable to human influence. In the West Cape region of South Africa, human influences increased the likelihood of the severe 2015–2017 drought by a factor of 3–6, depending on the analysis (Otto et al., 2018; Pascale et al., 2020). Anthropogenic forcing also contributed to the 2018 drought, mainly by increasing evapotranspiration (Nangombe et al., 2020). While some analysis of instrumental precipitation data in this region detect a slight long-term drying trend consistent with the simulated anthropogenic response (Seager et al., 2019b), there is strong multidecadal variability in the data (Wolski et al., 2020). However, an study of streamflow in southern Africa detected a significant decline (Gudmundsson et al., 2019) (see also Section 10.6.2). There is *medium confidence* in the long-term drying trend in this region and its attribution to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

anthropogenic forcing, and *medium confidence* that anthropogenic warming has contributed to recent severe drought events.

Several subtropical, semi-arid regions in the Southern Hemisphere have experienced long-term drying trends in the late 20th century. Southwestern South America (central Chile) experienced a multi-decadal decline in precipitation and streamflow culminating in a post-2010 megadrought that has been partly attributed to anthropogenic greenhouse gas emissions and ozone depletion (Boisier et al., 2016, 2018; Saurral et al., 2017; Knutson and Zeng et al., 2018; Seager et al., 2019b; Garreaud et al., 2020). There is *medium confidence* that drying in central Chile can be attributed to human influence. The tree-ring paleoclimate record demonstrates that the mid-century increase in exteme drought events in southern South America is unusual in the context of the last 600 years, suggesting an emerging influence of anthropogenic forcing (Morales et al., 2020).

There has been a 20% decrease in winter (May–July) rainfall in southwestern Australia since 1970, with the decline increasing to around 28% since 2000 (Delworth and Zeng, 2014; Bureau of Meteorology and CSIRO, 2020). There has also been a significant increase in the average intensity of seasonal droughts in the region since 1911in response to both lower precipitation and increased atmospheric evaporative demand (Gallant et al., 2013). Several studies attribute the precipitation declines in southwestern Australia to anthropogenic changes in GHG and ozone (Delworth and Zeng, 2014; Knutson and Zeng et al., 2018; Seager et al., 2019b). There is *high confidence* that the observed drying in southwestern Australia can be attributed to anthropogenic forcing.

In southeastern Australia, the average length of droughts have increased significantly, lasting between 10 and 69% longer than droughts during the first half of the 20th Century (Gallant et al., 2013). Paleoclimate reconstructions indicate a 97.1% probability that the decadal rainfall anomaly recorded during the 1997–2009 Millennium Drought in southeastern Australia was the worst experienced since 1783 (Gergis et al., 2012), and that the spatial extent and duration of cool season (April–September) rainfall anomalies were either very much below average or unprecedented over at least the last 400 years (Freund et al., 2017). Other paleoclimate studies suggest that the Millennium Drought in eastern Australia was not unusual in the context of natural variability reconstructed over the past millennium (Palmer et al., 2015; Cook et al., 2016c; Kiem et al., 2020). While there is currently *low confidence* that recent droughts in eastern Australia can be clearly attributed to human influences (Cai et al., 2014; Delworth and Zeng, 2014; Rauniyar and Power, 2020), there is emerging evidence that declines in April–October rainfall in southeastern Australia since the 1990s would not have been as large without the influence of increasing levels of atmospheric greenhouse gases (Rauniyar and Power, 2020).

In summary, it is *very likely* that anthropogenic factors have influenced global trends in aridity, mainly through competing changes in evapotranspiration and/or atmospheric evaporative demand due to anthropogenic emissions of GHG and aerosols. There is *high confidence* that the frequency and the severity of droughts has increased over the last decades in the Mediterranean, western North America, and southwestern Australia and that this can be attributed to anthropogenic warming. There is *medium confidence* that recent drying and severe droughts in southern Africa and southwestern South America can be attributed to human influence. In some regions of western North America and the Mediterranean, paleoclimate evidence suggests that recent warming has resulted in droughts that are of similar or greater intensity than those reconstructed over the last millennium (*medium confidence*).

[START FIGURE 8.9 HERE]

Figure 8.9: Spatial expressions (a-c; e-g) of the leading multivariate fingerprints of temperature (˚C), precipitation (mm/day), and aridity (CMI; the Climate Moisture Index) in CMIP5 historical simulations and the corresponding temporal evolution in both CMIP5 and reanalysis products (d, h). The first leading fingerprint is associated with greenhouse gas forcing (a-d) and the second leading fingerprint is associated with aerosol forcing (e-h). CMI is a dimensionless aridity indicator that combines precipitation and atmospheric evaporative demand. Figure after (Bonfils et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.9 HERE]

8.3.1.7 Freshwater reservoirs

8.3.1.7.1 Glaciers

AR5 and SROCC found, with *very high confidence,* a general decline in glaciers due to climate change in recent decades. There is *very high confidence* that during the decade 2010 to 2019 glaciers lost more mass than in any other decade since the beginning of the observational record (Chapter 2 section 2.3.2.3, Chapter 9 section 9.5.1. Human influence is *very likely* the main driver of the global, near-universal retreat of glaciers since the 1990s (Chapter 3, section 3.4.3.1). In Table 9.5, the contribution of glaciers to sea level rise for different periods is presented; in 1971-2018 glacier mass loss contributed 20.9 [10.0 to 31.7] mm or 22.1% of the sea level rise during that period. The highest mass loss rates are observed in the southern Andes, New Zealand, Alaska, Central Europe and Iceland while the largest mass loss are observed in Alaska, the periphery of Greenland and Arctic Canada (see section 9.5.1 and Figure 9.20). Predominantly, runoff from small glaciers such as in Canada has decreased because of glacier mass loss, while runoff from larger glaciers such as Alaska has typically increased (Bolch et al., 2010; Thomson et al., 2011; Tennant et al., 2012; WGMS, 2017; Huss and Hock, 2018). Asia contains the largest concentration of glaciers outside the polar regions where the total glacier mass change is −16.3 ± 3.5 Gt/yr over 2000-2016 with considerable intra-regional variability (Brun et al., 2017). Mass losses of glaciers in Asia between 2000 and 2018 are -19.0 +/-2.5 Gt/yr (Shean et al., 2020). The most negative changes were found in Nyainqentanglha with −4.0 ± 1.5 Gt/yr, while glaciers in Kunlun, northern Tibetan Plateau, slightly gained mass at 1.4 ± 0.8 Gt/yr.

There is some evidence that an increase of precipitation over high mountains can offset glacier ablation (melt) (Farinotti et al., 2020). However, this process has only been described from the Karakoram region in the northwestern Himalaya, where it is thought to be partly responsible to the advances of glacier changes in the last two decades, referred to as the 'Karakoram Anomaly' (Farinotti et al., 2020). In the Himalaya, Maurer et al. (2019) observed faster ice loss during 2000–2016 (–7.5 ± 2.3 Gt/yr) compared to 1975–2000 (–3.9 ± 2.2 Gt/yr). In the Southern Hemisphere, the rate of glacier mass lost in South America is estimated at 19.4 ± 0.6 Gt/yr based on surface elevation changes over 2000-2011, which include the North and South Patagonian Icefields of South America (Braun et al., 2019), and at −22.9 ± 5.9 Gt yr^{-1} over 2000-2018 (Dussaillant et al. 2019).

In summary, human-induced global warming has been the primary driver of a global glacier recession since the early 20th century (*high confidence*). Most glaciers have lost mass more rapidly since the 1960s and in an unprecedented way over the last decade, thereby contributing to increased glacier runoff, especially from larger glaciers until a maximum is reached, which tends to occur later in basins with larger glaciers and higher ice-cover fractions (*high confidence*).

8.3.1.7.2 Seasonal snow cover

AR5 assessed that Northern Hemisphere snow cover extent (SCE) has decreased since the late 1960s, especially in spring (*very high confidence*). This is confirmed by recent studies (Kunkel et al., 2016), (see also Chapter 2, Section 2.3.2.2). AR6 assesses that Northern Hemisphere spring snow cover has been decreasing since 1978 (*very high confidence*) and that this trend extends back to 1950 (*high confidence*) (see Section 9.5.3). Human-caused global warming is the dominant driver of this observed decline (Estilow et al., 2015) (see Section 3.4.2). Model simulations suggest that surface temperature responses at hemispheric/regional scales explain between 40% and 85% of the SCE trend variability (Mudryk, 2017). A decreasing trend in snowfall has also been detected in the Northern Hemisphere (Rupp et al., 2013) (Figure 8.1). Snowfall as a proportion of precipitation has decreased significantly in recent years (Berghuijs et al., 2014). However, a late 20th century increase in snowfall in West Antarctica observed in ice cores has been linked to a combination of factors including the anthropogenically forced deepening of the Amundsen Sea Low (Thomas et al., 2015, 2017).

Observations show a rapid recent decrease of spring SCE in Northern Hemisphere, mostly in Eurasia and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

North America, closely linked to temperature change, e.g., March–April SCE is decreasing at 3.4%±1.1% decade^{-1} (1979–2005) (Brown and Robinson, 2010; Hernández-Henríquez et al., 2015). An overall increasing annual trend of the Northern Hemisphere SCE since the late 1980s has been observed, in contrast to decreasing trends over 1960s-1980s that are dominated by the autumn and winter seasons (Barry and Gan, 2020). Such recent positive trends in snow cover extent are however at odds with other surface and satellite datasets and with the negative trends simulated by most CMIP5 and CMIP6 models (Mudryk et al., 2017, 2020). Hernández-Henríquez et al., (2015) also detected positive trends in October-November SCE in NOAA-CDR which are not replicated in other datasets (Section 9.5.3). Wu et al. (2018) found slower snowmelt rates over the Northern Hemisphere in 1980–2017, with higher ablation rates in locations with deep snow water equivalent (SWE), but due to the reduction of SWE in deep snowpacks, moderate/high ablation rates showed decreasing trends. Santolaria-Otín and Zolina, (2020) reported weak but significant decline in SCE in autumn over northern Eurasia and North America during 1979-2005, and similarly for spring, except for northern Siberia which showed higher spring SCE. Kapnick and Hall (2012) detected significant loss of spring mountain snowpack in western United States in 1950-2008. For Canada, extensive decreasing snow depths, SCE and duration were detected since mid-1970s, especially in western Canada during winter and spring (DeBeer et al., 2016). Berghuijs et al. (2014) show that across the continental United States, catchments with more snowfall than rainfall generally have higher mean streamflow, which will probably decrease with smaller fractions of precipitation falling as snow because of climate warming.

In summary, a decline in the springtime Northern Hemisphere snow cover extent, snow depth and duration has been observed since the late 1960s and has been attributed to human influence (*high confidence*). Depending on the region and season, there is *low-to-medium confidence* in the main drivers of snow cover changes, although various regions exhibit a shortening of the snow cover season which is consistent with global warming. A more detailed assessment of observed changes in seasonal snow cover is provided in Section 9.5.3.

8.3.1.7.3 Wetlands and lakes

Wetlands and lakes affect the climate through their impact on carbon and methane budgets (e.g. Saunois et al., 2016, Zhang et al., 2017) (Section 5.2.2) and on surface heat fluxes, with coupled weather and climate effects (e.g., Zhan et al., 2019). Although these features are also affected by human activities and by climate change, AR5 did not specifically report on wetlands and lakes.

Inventories of surface water bodies are not systematically produced at national or regional levels. However, assessments are undertaken at the global scale (Ramsar Convention on Wetlands, 2018). Merging observations from multiple satellite sensors makes it possible to detect surface water even under vegetation and clouds, over about 25 years but with low spatial resolution (Prigent et al., 2016). Most recent multi-satellite products from visible, infrared, and microwave measurements, estimate a surface water area of ~12-14 million km^2 (including permanent and transitory surfaces, e.g., Aires et al., 2018; Davidson et al., 2018), which is much higher than those provided by optical imagery (~3 million km^2). Inventories show a strong decrease in natural surface water of ~0.8% per year in total from 1970 to the present (Ramsar Convention on Wetlands, 2018) but the sites are not evenly distributed. Multi-satellite estimates show a strong inter-annual variability in surface water extent over the period 1992-2015 with no clear long-term trend (Prigent et al., 2020).

Human-made water bodies represent ~10% of the total continental water surfaces (Figure 8.1) (Ramsar Convention on Wetlands, 2018) and consist mainly of reservoirs and rice paddies. High resolution optical imagery over the period 1984-2015 (Donchyts et al., 2016; Pekel et al., 2016) shows that a net increase of ~ 0.1 million km^2 in artifical water surfaces, mainly due to the construction of reservoirs. Surfaces of rice paddies are also increasing, especially in South East Asia (Davidson et al., 2018).

In summary, there is *high confidence* that the extent of human-made surface water has increased over the 20th and early 21st century. In contrast, due to *limited agreement* in the observational records at the global scale, there is only *low confidence* in the observed decline of the natural surface water extent in recent years (see also SRCCL).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

8.3.1.7.4 Groundwater

As the world's most widespread store of freshwater (Taylor et al., 2013b), groundwater is estimated to supply between a quarter and a third of the world's annual freshwater withdrawals to meet agricultural, industrial and domestic demands (Döll et al., 2012; Wada et al., 2014; Hanasaki et al., 2018). Attribution of changes in groundwater storage, observed locally through piezometry (Taylor et al., 2013b) or estimated from GRACE satellite measurements (Rodell et al., 2018) at regional scales (> 100.000 km^2) (Figure 8.10), is often complicated by non-climate influences that include land-use change (Favreau et al., 2009) and human withdrawals (Bierkens and Wada, 2019).

Following a global review of groundwater and climate change (Taylor et al., 2013b) and AR5 WGII, evidence of an association between heavy or extreme precipitation and groundwater recharge has continued to grow, especially in tropical (Asoka et al., 2018; Cuthbert et al., 2019a; Kotchoni et al., 2019) and sub-tropical regions (Meixner et al., 2016). Stable-isotope ratios of O and H at 14 of 15 sites across the tropics trace groundwater recharge to intensive monthly rainfall, commonly exceeding the ~70th intensity percentile (Jasechko and Taylor, 2015). Further, heavy rainfall recharging groundwater resources is often influenced by climate variability such as ENSO and PDO (Taylor et al., 2013c; Kuss and Gurdak, 2014; Asoka et al., 2017; Cuthbert et al., 2019b; Kolusu et al., 2019; Shamsudduha and Taylor, 2020). Additionally, increases in groundwater storage estimated from GRACE for 37 of the world's large-scale aquifer systems from 2002 to 2016 are generally found to result from episodic recharge associated with extreme (>90th percentile) annual precipitation.

The overall underestimation of precipitation intensities in global climate models (Wehner et al., 2010, 2020; Goswami and Goswami, 2017) and of their sensitivity to warming temperatures (Borodina et al., 2017) may lead to underestimates of their recharging effect on groundwater (Mileham et al., 2009; Cuthbert et al., 2019b). The limited ability of global climate models to represent key controls on regional rainfall variability like ENSO (Chen et al., 2020d) (Technical Annex VI, Section 3.7.3) may also underestimate observed recharge from such events that are of particular importance in drylands (Taylor et al., 2013c; Cuthbert et al., 2019b). Numerical representations of the impact of precipitation intensification on groundwater recharge in large-scale models remain constrained by the challenges of including key recharge pathways that consider preferential flowpaths in soils (Beven, 2018) and focused recharge through leakage from surface waters (Döll et al., 2014).

Increasing global freshwater withdrawals, primarily associated with the expansion of irrigated agriculture in drylands, have led to global groundwater depletion that has an estimated range of ~100 and ~300 km^3 yr^{-1} from hydrological models and volumetric-based calculations (Bierkens and Wada, 2019). The magnitude of this change is such that its estimated contribution to global sea-level rise is in the order of 0.3 to 0.9 mm yr^{-1} (Wada et al., 2010; Konikow, 2011; Döll et al., 2014; Pokhrel et al., 2015; de Graaf et al., 2017; Hanasaki et al., 2018). Groundwater depletion has been observed regionally in the United States High Plains, California's Central Valley (Scanlon et al., 2012), northwest India (Rodell et al., 2009; Asoka et al., 2017), Upper Ganges in India (MacDonald et al., 2016), North China Plain (Feng et al., 2013), north-central Middle East region of Tigris-Euphrates-Western Iran (Voss et al., 2013), Central Asia (Hu et al., 2019), and North Africa (Bouchaou et al., 2013). The regional contribution of agricultural irrigation to groundwater depletion was previously highlighted by SRCCL but no formal assessment of observed changes in global or regional groundwater featured in AR5.

Quantification of changes in groundwater storage from GRACE is currently constrained by uncertainty in the estimation of changes in other terrestrial water stores using uncalibrated, global-scale Land Surface Models (Döll et al., 2014; Scanlon et al., 2018) and the limited duration of the period of GRACE observations (2002 to 2016). Centennial-scale piezometry in northwest India reveals that recent groundwater depletion traced by GRACE (Rodell et al., 2009; Chen et al., 2014), follows more than a century of groundwater accumulation through canal leakage (MacDonald et al., 2016). Further, groundwater depletion is often localised occurring below the footprint (200.000 km^2) of GRACE, as has been well demonstrated by detailed modelling studies in the California Central Valley (Scanlon et al., 2012) and North China Plain (Cao et al., 2016).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Climate variability and drought affect groundwater depletion mainly due to amplified groundwater withdrawals. For instance, the depletion rate in Central Valley aquifer in the USA from 2006 to 2010 is estimated to range from 6 to 8 km^3 yr^{-1} using GRACE data (Scanlon et al., 2012). In India, Asoka et al. (2017) show contrasting trends in groundwater storage in the north (declining at 2 cm yr^{-1}) and south (increasing at 1-2 cm yr^{-1}) that is explained by variations in human withdrawals and precipitation linked to Indian Ocean sea surface temperature variability.

Changes in meltwater regimes from glaciers and seasonal snow packs tend to reduce the seasonal duration and magnitude of recharge (Tague and Grant, 2009). Aquifers in mountain valleys show shifts in the timing and magnitude of: (1) peak groundwater levels due to an earlier spring melt; and (2) low groundwater levels associated with lower baseflow periods (Allen et al., 2010; Dierauer et al., 2018; Hayashi, 2020). The effects of receding alpine glaciers on groundwater systems are not well understood but long-term loss of glacier storage is estimated to reduce summer baseflow (Gremaud et al., 2009). In permafrost regions, coupling between surface-water and groundwater systems may be particularly enhanced by warming (Lamontagne-Hallé et al., 2018; Lemieux et al., 2020). In areas of seasonal or perennial ground frost, increased recharge is expected despite a decrease in absolute snow volume (Okkonen & Kløve, 2011; Walvoord & Kurylyk, 2016).

Coastal aquifers are the interface between the oceanic and terrestrial hydrological systems. Global sea level rise (SLR) causes fresh–saline-water interfaces to move inland. The extent of seawater intrusion into coastal aquifers depends on a variety of factors including coastal topography, recharge, and groundwater abstraction from coastal aquifers (Comte et al., 2016). Modelling results suggest that the impact of SLR on seawater intrusion is negligible compared to that of groundwater abstraction (Ferguson & Gleeson, 2012; Yu & Michael, 2019). Coastal aquifers under very low hydraulic gradients, such as the Asian mega-deltas, are theoretically sensitive to SLR but, according to evidence from Akter et al. (2019) in the Ganges-Brahmaputra-Megna Basin, may be more severely and widely affected by changes in upstream river discharge. They argue further that saltwater inundation from storm surges will have the greatest localised effects.

In summary, there is *medium confidence* that increased precipitation intensities, partly due to human influence, have enhanced groundwater recharge, most notably in the tropics. There is *high confidence* that groundwater depletion has occurred since at least the start of the 21st century as a consequence of groundwater withdrawals for irrigation in some of the world's most productive agricultural areas in drylands (e.g. southern High Plains and California Central Valley in the USA, the North China Plain, northwest India).

[START FIGURE 8.10 HERE]

Figure 8.10: Trends in Terrestrial Water Storage (TWS) (in centimetres per year) obtained on the basis of GRACE observations from April 2002 to March 2016. The cause of the trend in each outlined study region is briefly explained and colour-coded by category. The trend map was smoothed with a 150-km-radius Gaussian filter for the purpose of visualization; however, all calculations were performed at the native 3° resolution of the data product. Figure from Rodell et al. (2018). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END OF FIGURE 8.10 HERE]

8.3.2 Observed variations in large-scale phenomena and regional variability

Observed changes in large-scale circulation indicators (Cross-Chapter Box 2.2) are assessed in Chapters 2 and 3 (see Sections 2.3.1.4 and 3.3.3). In this chaper we focus on the influence of regional scale teleconnection variabililty on the water cycle and the attribution of these circulation changes. While

ACCEPTED VERSION SUBJECT TO FINAL EDITING

observed changes in modes of variability are assessed in Chapters 2 and 4 (see Sections 2.4 and 4.3.3), here focus on hydrological teleconnections of relevance to the water cycle.

8.3.2.1 Intertropical Convergence Zone (ITCZ) and tropical rain belts

AR5 concluded it is *likely* that the tropical belt, as delimited by the Hadley circulation, has widened since the 1970s. Observations in the satellite era indicate precipitation increases in the core of the Pacific ITCZ and decreases on the ITCZ margins (Gu et al., 2016; Su et al., 2017). As the satellite period has lengthened, observations have increasingly been used to assess trends in the ITCZ and tropical rain belt. Since AR5, significant narrowing and strengthening of the Pacific ITCZ after 1979 have been identified in atmospheric reanalyses (Wodzicki and Rapp, 2016), but no change in the ITCZ location (Byrne et al., 2018). Atmospheric model simulations suggest that with a narrower ITCZ, the subtropical jet becomes baroclinically unstable at a lower latitude and allows midlatitude eddies to propagate farther equatorward (Watt-Meyer and Frierson, 2019). Observational analyses also show that the ITCZ narrowing (Zhou et al., 2020) is associated with increased precipitation in the ITCZ core region that is strongly coupled to increasing Outgoing Longwave Radtion (OLR) in the expanding dry zones, particularly over land regions in the subtropics and midlatitudes (Lau and Tao, 2020). In addition, an eastward movement of the South Pacific Convergence Zone (SPCZ) between 1977 and 1999 has been reported, with associated significant precipitation trends in the South Pacific regions (Salinger et al., 2014).

ITCZ trends seen in satellites, precipitation measurements and reanalysis data are further supported by ocean surface-salinity observations. Long-term salinity observations show a freshening in the cores of the Atlantic and Pacific ITCZs and increased salinity on the ITCZ margins (Durack et al., 2010, 2012; Terray et al., 2012; Skliris et al., 2014). By investigating simultaneous changes in precipitation, temperature and continental aridity in CMIP5 historical simulations, Bonfils et al. (2020a) found a secondary signal (Figure 8.9, right column) characterized by a robust interhemispheric temperature contrast (Section 3.3.1.1), a latitudinal shift in the ITCZ (in accordance with the theory of cross-equatorial energy transport; Section 8.2.2.2), and changes in aridity in the Sahel (section 8.3.1.6). These forced changes are statistically detectable in reanalyses datasets over the 1950-2014 period at the 95% confidence level.

Reconstructions in the Sahel (Carré et al., 2019) and Belize (Ridley et al., 2015) support the southward displacement of the tropical rain belt since 1850 and the narrowing trend of the tropical rainbelt detected in observations (Rotstayn et al., 2002; Hwang et al., 2013). Decreasing precipitation trends in the Northern Hemisphere during the 1950s-1980s have been attributed to anthropogenic aerosol emissions from North America and Europe, which peaked during the late1970s and declined thereafter following improved air quality regulations, causing dimming (brightening) through reduced (increased) surface solar radiation (Box 8.1 Figure 1), in agreement with model simulations (Chiang et al., 2013; Hwang et al., 2013). This is consistent with energetic constraints where tropical precipitation shifts are anti-correlated with cross-equatorial energy transport (Section 6.3.3, Box 8.1). It also provides a physical mechanism for the severe drought in the Sahel that peaked in the mid-1980s (Sections 8.3.2.4.3 and 10.4.2.1) and the southward shift of the Northern Hemisphere tropical edge from the 1950s to the 1980s (Allen et al., 2014; Brönnimann et al., 2015). However, CMIP5 and CMIP6 models still exhibit strong biases in the representation the ITCZ, such as the simulation of a double ITCZ (Oueslati and Bellon, 2015; Adam et al., 2018; Tian and Dong, 2020). The impacts of aerosols and volcanic activity on the position of the ITCZ have been investigated but changes are difficult to characterize from observations (Friedman et al., 2013; Haywood et al., 2013b; Iles et al., 2014; Colose et al., 2016; Chung and Soden, 2017) (see Section 6.3.3.2). Such systematic shifts of the ITCZ can have important regional impacts like changes in precipitation (Figure 8.9).

In summary, there is *medium confidence* that the tropical rain belts over the oceans have been narrowing and strengthening in recent decades, leading to increased precipitation in the ITCZ core region (see also Section 8.2.2.2). Decreasing precipitation trends in the Northern Hemisphere during the 1950s-1980s have been attributed to anthropogenic aerosol emissions from North America and Europe (*high confidence)*.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

8.3.2.2 Hadley circulation and subtropical belt

AR5 reported *low confidence* in trends in the strength of the Hadley Circulation (HC) due to uncertainties in reanalyses but *high confidence* on the widening of the tropical belt since 1979. In AR6, Chapter 2 (see section 2.3.1.4.1) states that the HC has *very likely* widened and strengthened since at least the 1980s, mostly in the Northern Hemisphere (*medium confidence*).

The poleward shift of the HC is closely related to migration of the location of tropical cyclone trajectories in both hemispheres (Studholme and Gulev, 2018; Sharmila and Walsh, 2018), with a *very likely* poleward shift over the western North Pacific Oceans since the 1940s (Section 11.7.1.2). Moreover, the Western North Pacific Subtropical High has extended westward since the 1970s, resulting in a monsoon rain band shift over China, with excessive rainfall along the middle and lower reaches of the Yangtze River valley along ~ 30°N over eastern China. At the same time, the effect of anthropogenic aerosols dominated the response to GHG increases over East Asia, resulting in a weakening of the East Asian summer monsoon and causing a drying trend in northeastern China (Hu, 2003; Yu and Zhou, 2007; Wang et al., 2013b; Li et al., 2016c; Lau and Kim, 2017) and northern parts of South Asia (Preethi et al., 2017) (see also Section 8.3.2.4.2). During 1977-2007, the precipitation variability over the eastern United States increased due to changes in the intensity and position of the western ridge of the North Atlantic Subtropical High (Li et al., 2011; Diem, 2013).

In the Southern Hemisphere, the HC expansion has been associated with both the intensification and poleward shift of the subtropical high pressure belt (Nguyen et al., 2015), with consequences for precipitation amount over Africa, Australia, South America, and subtropical Pacific islands (Cai et al., 2012; Grose et al., 2015; Nguyen et al., 2015; Sharmila and Walsh, 2018; McGree et al., 2019). The subtropical ridge in Australia has intensified significantly since 1970, with marked declines observed in April to October rainfall across southeastern and southwestern Australia (Timbal and Drosdowsky, 2013).

The local tropical edges of the meridional overturning cells (as diagnosed from the horizontally divergent wind) are more closely associated with hydroclimate variations than the subtropical ridge (Staten et al., 2019). Poleward expansion of the tropical belt strongly contributes to precipitation decline in the poleward edge of the subtropics (Cai et al., 2012; Scheff and Frierson, 2012; Timbal and Drosdowsky, 2013; He and Soden, 2017; Nguyen et al., 2018a; Tang et al., 2018), although recent modelling evidence suggests that subtropical precipitation declines are a response to direct CO_2 radiative forcing mainly over ocean, irrespective of the HC expansion (He and Soden, 2017). Both reanalyses datasets and climate model simulations suggest that the HC expansion is not associated with widespread, zonally symmetric subtropical drying over land (Schmidt and Grise, 2017).

Since AR5, an improved understanding of the key drivers of the recent HC expansion has been achieved, identifying the role of both internal variability and anthropogenic climate change. Part of the recent expansion (1979-2005) of the HC has been driven by a swing from warm to cold phase of the Pacific Decadal Variability (PDV) (Meehl et al., 2016; Grise et al., 2019). The presence of large multidecadal variability in 20th century reanalyses means there is *limited evidence* on the human influence on the recent HC strengthening, yet the southward shift of the southern edge and widening of the Southern Hemisphere HC appeared as robust features in all reanalysis datasets, and their trends have accelerated during 1979-2010 (D'Agostino and Lionello, 2017). As assessed in Section 3.3.3.1, GHG increases and stratospheric ozone depletion have contributed to the expansion of the zonal mean HC in the Southern Hemisphere since around 1980, and the expansion of the Northern Hemisphere HC has not exceeded the range of internal variability (*medium confidence*). Moreover, Antarctic ozone depletion can cause a poleward shift in the Southern Hemisphere midlatitude jet and HC (Sections 3.3.3 and 6.3.3.2). Further assessment of the attribution of recently observed changes in the HC extent and intensity is found in Section 3.3.3.1.

In summary, it is *very likely* that the recent Hadley Circulation (HC) expansion was associated with poleward shifts of tropical cyclone tracks over the western North Pacific Ocean since the 1940s, and of extratropical storm tracks in the Southern Hemisphere since the 1970s. Changes to the HC in the Northern Hemisphere may have contributed to subtropical drying and a poleward expansion of aridity during the boreal summer, but there is *low confidence* due to *limited evidence*. GHG increases and stratospheric ozone depletion have

ACCEPTED VERSION SUBJECT TO FINAL EDITING

contributed to expansion of the zonal mean HC in the Southern Hemisphere since around 1970, while the expansion of the Northern Hemisphere HC has not exceeded the range of internal variability (*medium confidence*).

8.3.2.3 Walker circulation

AR5 concluded that the long-term weakening of the Pacific Walker Circulation (WC) from the late 19th century to the 1990s has been largely offset by a recent strengthening (*high confidence*), though with *low confidence* in trends of the WC strength due to reanalysis uncertainties and large natural variability. The observed trends in the WC since 1980 are consistent with a *very likely* WC strengthening in the Pacific, similar to a La Niña pattern, with *medium confidence* in the magnitude of these changes due to differences between satellite observations and reanalyses.

The causes of the observed strengthening of the Pacific WC during 1980-2014 are not well understood due to competing influences from individual external forcings and since this strengthening is outside the range of variability simulated in coupled models (*medium confidence*), as assessed in Chapter 3 (see Section 3.3.3.1). Recent strengthening in the WC has been linked with internal variability (Chung et al., 2019), although one study argues that it could be a response forced by GHG that models do not capture because of common SST biases in the equatorial Pacific (Seager et al., 2019a). It could be also related to an interbasin thermostat mechanism whereby the human-induced Indian Ocean warming emerged earlier than in the tropical Pacific (Zhang et al., 2018b) and induced a transient strengthening of the zonal sea level pressure gradient and easterly trades in the tropical Pacific (Zhang et al., 2019a).

The weakening of the WC observed during most of the 20th century is associated with reductions in land rainfall over the Maritime Continent during 1950-1999 (Tokinaga et al., 2012; Yoden et al., 2017). In contrast, the recent strengthening of the WC has been associated with an intensification of extreme flooding (Barichivich et al., 2018) and an increased frequency of wet days (Espinoza et al., 2016, 2018a) over the northwestern Amazon, increased precipitation in South America (Yim et al., 2017), reduced precipitation over eastern Africa (Williams and Funk, 2011; Lyon and Dewitt, 2012), and increased rainfall in southern Africa (Maidment et al., 2015). Internal variability has been shown to have a dominant role in the recent strengthening of the WC (Chung et al., 2019).

In summary, there is *high confidence* that changes in the Pacific Walker Circulation (WC) are associated with changes in the water cycle over regions like the Maritime Continent, South America and Africa. It is *very likely* that the WC has strengthened in the Pacific since the 1980s, with *medium confidence* that this strengthening is within the range of internal variability.

8.3.2.4 Monsoons

AR5 reported *low confidence* in the attribution of changes in monsoons to human influences, although a detailed attribution assessment of the observed changes in the regional monsoons was not presented.

Large human populations in the monsoon regions of the world heavily depend on freshwater supply for agriculture, water resources, industry, transport and various socio-economic activities. The effects of GHG forcing combined with water vapour feedback (Allen et al., 2015b; Dong and Sutton, 2015; Evan et al., 2015; Dunning et al., 2018) and cloud feedbacks (Stephens et al., 2015; Potter et al., 2017) are fundamental to monsoon precipitation changes in a warming world. Since AR5 there has been improved understanding of precipitation changes associated with regional monsoons. Sections 2.3.1.4.2 and 3.3.3.2 provide an assessment of observed changes and attribution for the global monsoon. Here we provide an assessment of the observed changes in regional monsoons (see Annex V and Figure 8.11) and underlying causes. In AR6, the definition of regional monsoons slightly differs from AR5 and the rationale for it is provided in Annex V (see also Annex VII: Glossary). Specific examples of regional monsoons are discussed further in section 10.4.2, from the perspective of climate change attribution and in section 10.6.3, from the viewpoint of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

constructing regional climate messages.

[START FIGURE 8.11 HERE]

Figure 8.11: Regional monsoon precipitation changes from observations and model attribution. Precipitation changes during 1951-2014 are shown as least-square linear trends in box-whisker plots (first and fourth rows) over the six regional monsoons, i.e., North American monsoon (NAmerM, Jul-Aug-Sep), West African monsoon (WAfriM, Jun-Jul-Aug-Sep), South and Southeast Asian monsoon (SAsiaM, Jun-Jul-Aug-Sep), East Asian monsoon (EAsiaM, Jun-Jul-Aug), South American monsoon (SAmerM, Dec-Jan-Feb), Australian and Maritime Continent monsoon (AusMCM, Dec-Jan-Feb), and over the two land domains (i.e. equatorial America (EqAmer, Jun-Jul-Aug) and South Africa (SAfri, Dec-Jan-Feb), as identified in the map shown in the middle and as described in Annex V. Precipitation changes are computed from observations and from DAMIP CMIP6 experiments over the historical period with all-forcing (ALL), GHG-only forcing (GHG), Aerosol-only (AER) and Natural (NAT) forcings prescribed. Observations are based on the CRU (light green) and GPCC (light blue) datasets and the APHRODITE (light orange) dataset for SAsiaM and EAsiaM. CMIP6 simulations are taken from nine CMIP6 models contributing to DAMIP, with at least 3 members. Ensembles are weight-averaged for the respective model ensemble size. Observed trends are shown as coloured cirles and the simulated trends from the CMIP6 multi-model experiments are shown as box-whisker plots. Precipitation anomaly time-series are shown in the second and third row. The thick black line is the multi-model ensemble-mean precipitation anomaly time-series from the ALL experiment and the grey shading shows the spread across the multi-model ensembles. A 11-year running mean has been applied on the precipitation anomaly time-series prior to calculating the multi-model ensemble mean. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.11 HERE]

8.3.2.4.1 South and Southeast Asian Monsoon

AR5 reported a decreasing trend of global land monsoon precipitation over the last half-century, with primary contributions from the weakened summer monsoon systems in the Northern Hemisphere. Since AR5, several studies have documented long-term variations and changes in the South and Southeast Asian Summer Monsoon (SAsiaM) rainfall. The SAsiaM strengthened during past periods of enhanced summer insolation in the Northern Hemisphere, such as the early-to-mid Holocene warm period around 9000 to 6000 years BP (Masson-Delmotte et al., 2013; Mohtadi et al., 2016; Braconnot et al., 2019) and weakened during cold periods (*high confidence*), such as the Last Glacial Maximum (LGM) and Younger Dryas (Shakun et al., 2007; Cheng et al., 2012; Dutt et al., 2015; Chandana et al., 2018; Hong et al., 2018; Zhang et al., 2018a). These long time-scale changes in monsoon intensity are tightly linked to orbital forcing and changes in high-latitude climate (Braconnot et al., 2008; Battisti et al., 2014; Araya-Melo et al., 2015; Rachmayani et al., 2016; Bosmans et al., 2018; Zhang et al., 2018a). A weakening trend of the SAsiaM during the last 200 years has been documented based on tree ring oxygen isotope chronology from the northern Indian subcontinent (Xu et al., 2018) and Southeast Asia (Xu et al., 2013), oxygen isotopes in speleothems from northern India (Sinha et al., 2015), and tree ring width chronologies from the Indian core monsoon region (Shi et al., 2017). Nevertheless, the detection of century-long decreases in regional monsoon rainfall is obscured by the presence of multidecadal time-scale precipitation variations (Turner and Annamalai, 2012; Knutson and Zeng et al., 2018) which are evident in long-term rain guage records extending back to the early 1800s (Sontakke et al., 2008) and emerge in long-term climate simulations (Braconnot et al., 2019).

A significant decline in summer monsoon precipitation is observed over India since the mid-20th century, which is accompanied by a weakening of the large-scale monsoon circulation (Mishra et al. et al., 2012; Abish et al., 2013; Krishnan et al., 2013, 2016; Saha et al., 2014; Roxy et al., 2015; Guhathakurta et al. et al., 2017; Samanta et al. et al., 2020). This precipitation decline is corroborated by a decreasing trend in the frequency of monsoon depressions that form over Bay of Bengal (Prajeesh et al., 2013; Vishnu et al., 2016), an increasing trend in the frequency and duration of monsoon breaks or 'dry spells' (Singh et al., 2014), significant decreases in soil moisture and increases in drought severity across different parts of India post-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

1950 (Niranjan Kumar et al., 2013; Ramarao et al., 2015; Krishnan et al., 2016; Ramarao et al., 2018; Ganeshi et al., 2020; Mujumdar et al., 2020). While recent studies have reported an apparent recovery of the Indian summer monsoon over a relatively short period since 2003 (Jin and Wang, 2017; Hari et al., 2020), long-term trends for the period 1951-2015 indicate an overall decrease in the regional monsoon precipitation (Kulkarni et al., 2020; Ayantika et al et al., 2021). A case study on the Indian summer monsoon is provided in Section 10.6.3.

Evidence from several climate modelling studies indicates that the observed decrease in the regional monsoon precipitation during the second half of the 20th century is dominated by the radiative effects of Northern Hemisphere anthropogenic aerosols, with smaller contributions due to volcanic aerosols from the Mount Pinatubo (1991) and El Chichon (1982) eruptions (Bollasina et al. et al., 2011; Polson et al. et al., 2014a; Sanap et al., 2015; Krishnan et al., 2016; Liu et al., 2016; Lau and Kim, 2017; Undorf et al., 2018; Undorf et al. et al., 2018; Lin et al., 2018; Takahashi et al., 2018; Patil et al., 2019; Singh et al., 2020b) (Box 8.1 Figure 1, Figure 8.11). Land-use changes over South and Southeast Asia and the rapid warming trend of the equatorial Indian Ocean during the recent few decades also appear to have contributed to the observed decrease in monsoon precipitation (Roxy et al., 2015; Krishnan et al., 2016; Singh, 2016). Overall, the magnitude of the precipitation response to anthropogenic forcing exhibits large spread across CMIP5 models pointing to the strong internal variability of the regional monsoon (Saha et al., 2014; Salzmann et al., 2014; Sinha et al., 2015), including variations linked to phase changes of the Pacific interdecadal variability (Section AVI.2.6) (Huang et al., 2020b), uncertainties in representing aerosol-cloud interactions (Takahashi et al., 2018), and the effects of local versus remote aerosol forcing (Bollasina et al. et al., 2014; Polson et al. et al., 2014b; Undorf et al., 2018). CMIP3 and CMIP5 models do not accurately reproduce the observed seasonal cycle of precipitation over the major river basins of South and Southeast Asia, limiting the attribution of observed regional hydroclimatic changes (Hasson, 2014; Hasson et al., 2016; Biasutti, 2019). While warm rain processes and organized convection are known to dominate the heavy orographic monsoon rainfall over the Western Ghats mountains (Shige et al., 2017; Choudhury et al., 2018), in various parts of India (Konwar et al., 2012) and East Asia (Section 11.7.3.1), there are uncertainties in representing the regional physical processes of the monsoon environment, including cloud-aerosol interactions (Sarangi et al., 2017), land-atmosphere (e.g., Barton et al., 2020) and ocean-atmosphere coupling (Annamalai et al., 2017), in state-of-the-art climate models (See also Section 8.5.1).

In summary, there is *high confidence* in observational evidence for a weakening of the SAsiaM in the second half of the 20th century. Results from climate models indicate that anthropogenic aerosol forcing has dominated the recent decrease in summer monsoon precipitation, as opposed to the expected intensification due to GHG forcing (*high confidence*). On paleoclimate timescales, the SAsiaM strengthened in response to enhanced summer warming in the NH during the early-to-mid Holocene, while it weakened during cold intervals (*high confidence*). These changes are tightly linked to orbital forcing and changes in high-latitude climate (*medium confidence*).

8.3.2.4.2 East Asian Monsoon

AR5 reported *low confidence* in the observed weakening of the East Asian Monsoon (EAsiaM) since the mid-20th century. Since AR5, there has been improved understanding of changes in the EAsiaM, based on paleoclimatic evidence, instrumental observations and climate modeling simulations. Rainfall reconstructions from the Loess Plateau in China indicate that the northern extent of the monsoon rain belts migrated at least 300 km to the northwest from the LGM to the mid-Holocene (Yang et al., 2015). Similarly, Pliocene reconstructions indicate stronger intensity of the EAsiaM with a more northward penetration of the monsoon rain belt (Yang et al., 2018b). EAsiaM variability has been related to AMOC dynamics, especially during the last glacial period, but whether the relationship is negative or positive remains uncertain (Sun et al., 2012; Cheung et al., 2018; Kang et al., 2018).

Long-term precipitation observations from China indicate a trend of drying in the north and wetting in the central-eastern China along the Yangtze river valley since the 1950s (Qian and Zhou, 2014; Zhou et al., 2017a; Day et al., 2018), with a weakened EAsiaM low-level circulation that penetrates less far into northern China, increased surface pressure over northeast China and southward shift of the jet stream (Song et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2014). The southward shift and enhancement of the jet stream explains the increase of rainfall especially from the Meiyu front (Day et al., 2018) at the expense of drying over northeast China.

Anthropogenic factors such as GHGs and aerosols had an influence on the EAsiaM changes (Wang et al., 2013b; Song et al., 2014; Xie et al., 2016; Chen and Sun, 2017; Ma et al., 2017; Zhang et al., 2017a; Day et al., 2018; Tian et al., 2018) (Figure 8.11). Increased precipitation in the southern region has been linked to increased moisture flux convergence driven by GHG forcing whilst changes in anthropogenic aerosols have weakened the EAsiaM and reduced precipitation in the northern regions (Tian et al., 2018). Aerosol-induced cooling, associated atmospheric circulation changes and SST feedbacks weaken the EAsiaM and favour the observed dry-north and wet-south pattern of rainfall anomalies (Wang et al., 2013b; Song et al., 2014; Zhang et al., 2017a; Chen et al., 2018a, 2018b; Undorf et al., 2018).

Internal variability and volcanic eruptions also contributed to the weakened EAsiaM (Hsu et al., 2014; Qian and Zhou, 2014; Zhou et al., 2017b; Knutson and Zeng et al., 2018). Since the late 1970s, the EAsiaM weakening has been also linked to SST changes in the Pacific Ocean with warm conditions in the central-eastern tropical part and cold ones in the north, similar to a positive phase of the Pacific Decadal Variability (PDV, Section AVI.2.6) (Li et al., 2016c; Zhou et al., 2017b). In the late 1990s the transition from a positive to a negative PDV has been associated to the recent recovery observed in the EAsiaM strength (Zhou et al., 2017b). Atlantic Multidecadal Variability (AMV) also has an influence on the EAsiaM via the global teleconnection pattern propagating from the North Atlantic through the westerly jet (Zuo et al., 2013; Wu et al., 2016a, 2016b). This North Atlantic influence has contributed to the increase of precipitation over the Huaihe-Huanghe valley since the late 1990s (Li et al., 2017c). When PDV and AMV are in opposite phase, the former has a larger influence in driving the southern flooding and northern drought pattern over the region (Yang et al., 2017b).

In summary, there is strong evidence of a stronger EAsiaM and northward migration of the rainbelt during warmer climates based on paleoclimate reconstructions. There is *high confidence* that anthropogenic forcing has been influencing historical EAsiaM changes with drying in the north and wetting in the south observed since the 1950s, but there is *low confidence* in the magnitude of the anthropogenic influence. The transition towards a positive Pacific Decadal Variability phase has been one of the main drivers of the EAsiaM weakening since the 1970s *(high confidence)*.

8.3.2.4.3 West African Monsoon

Since AR5, there has been improved understanding of the West African Monsoon (WAfriM) response to natural and anthropogenic forcing. On paleoclimate timescales, enhanced summer insolation in the Northern Hemisphere intensified the WAfriM precipitation during the early-to-mid Holocene (*high confidence*), as seen in rainfall proxy records and climate model simulations (Masson-Delmotte et al., 2013; Mohtadi et al., 2016; Braconnot et al., 2019). Despite improvements in model simulations of the present-day monsoons, CMIP5 and CMIP6 models underestimate mid-Holocene changes in the amount and spatial extent of the WAfriM precipitation (Brierley et al., 2020) (Section 3.3.3.2).

During the recent past, long-term rain gauge observations display substantial variability in the WAfriM precipitation over the 20th century (Section 10.4.2.1). The WAfriM experienced the wettest decade of the 20th century during the 1950s and early 1960s (*high confidence*), over much of the western and central Sahel region, followed abruptly by the driest years during 1970-1989 (Ali and Lebel et al., 2009; Nicholson, 2013; Descroix et al., 2015). The percentage deficit in the annual rainfall during 1970-1989, relative to the long-term mean, ranged from 60% in the north of Sahel to 25-30% in the south (Le Barbé et al., 2002; Lebel et al., 2003). The long decline in annual rainfall is related to a decrease of rain occurrence over the Sahel (Le Barbé and Lebel, 1997; Frappart et al., 2009; Bodian et al., 2016) and the Soudano-Guinean sub-region of West-Africa (Le Barbé et al., 2002), even though the interannual variability pattern is more complex (Balme et al., 2006). Decrease of rainfall occurrences resulted from decreases in large convective events in the core of the rainy season (Bell et al., 2006), that modulate interannual variability of the WAfriM (Panthou et al., 2018).

Wetter conditions of the WAfriM prevailed later from the mid-to-late 1990s, although the positive trend in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

precipitation started since late 1980s (see also Section 10.4.2.1) over the Sahel (*high confidence*) and in the Guinean coastal region (*medium confidence*), indicating the geographical variation in the wetting recovery (Descroix et al., 2015; Sanogo et al., 2015; Bodian et al., 2016; Nicholson et al., 2018). While the interannual and decadal variability of annual rainfall is not homogeneous over the entire Sahel, the rainfall recovery was stronger in the east than in the west of the region (Nicholson et al., 2018) (Section 10.4.2.1). A shift in the seasonality of the Sahelian rainfall, including delayed cessation has also been reported (Nicholson, 2013; Dunning et al., 2018) (see also Section 10.4.2.1).

In the Sahel region, the emergence of this new rainfall regime is reflected in increased number of heavy and extreme events, compared to the 1970s-1980s, still not exceeding the values registered in the 1950s-1960s (Descroix et al., 2013, 2015, Panthou et al., 2014, 2018; Sanogo et al., 2015), and in higher interannual variability (Zhang et al., 2017b; Akinsanola and Zhou, 2020) associated with SST variations in the tropical Atlantic, Pacific and Mediterranean Sea (Rodríguez-Fonseca et al., 2015; Diakhate et al, 2019). Increased frequency of extreme rainfall events impacts high flow occurrences of the large Sahelian rivers as well as small to meso-scale catchments (Wilcox et al., 2018a). Overall, extreme intense precipitation events are more frequent in the Sahel since the beginning of the 21st century (Giannini et al., 2013; Panthou et al., 2014, 2018; Sanogo et al., 2015; Taylor et al., 2017). Intensification of mesoscale convective systems associated with extreme rainfall in the WAfriM is favoured by enhancement of meridional temperature gradient by the warming of the Sahara desert (Taylor et al., 2017) at a pace that is 2–4 times greater than that of the tropical-mean temperature (Cook et al., 2015c; Vizy et al., 2017). Periods of monsoon-breaks and the persistence of low rainfall events are still prominent, particularly after the onset, thus exposing West Africa simultaneously to the potential impacts of dry spells (Zhang et al., 2017b) and also extreme localized rains and floods (Engel et al., 2017; Lafore et al., 2017). Occurrence of extreme events is compounded by land use and land cover changes leading to increased runoff (Bamba et al., 2015; Descroix et al., 2018).

The Sahel drought from the 1970s until the early 1990s was related to anthropogenic emissions of sulphate aerosols in the Atlantic, which led to an inter-hemispheric pattern of SST anomalies and associated regional precipitation changes (Box 8.1; Section 6.3.3.2). Also the combined effects of anthropogenic aerosols and GHG forcing appear to have contributed to the late twentieth century drying of the Sahel through their effect on SST, by cooling the North Atlantic and warming the tropical oceans (Giannini and Kaplan, 2019; Hirasawa et al., 2020). Subsequent aerosol removal led to SST warming of the North Atlantic, shifting the ITCZ further northward and strengthening the WAfriM (Giannini and Kaplan, 2019). The recent recovery has been ascribed to prevailing positive SST anomalies in the tropical North Atlantic potentially associated with a positive phase of the Atlantic multidecadal oscillation (Diatta and Fink, 2014; Rodríguez-Fonseca et al., 2015). The Sahel rainfall recovery has also been attributed to higher levels of GHG in the atmosphere and increases in atmospheric temperature (Dong and Sutton, 2015).

In summary, most regions of West Africa experienced a wet period in the mid-20th century followed by a very dry period in the 1970s and 1980s that is attributed to aerosol cooling of the Northern Hemisphere (*high confidence*). Recent estimates provide evidence of a WAfriM recovery from the mid-to-late 1990s, with more intense extreme events partly due to the combined effects of increasing GHG and decreasing anthropogenic aerosols over Europe and North America (*high confidence*). On paleoclimate timescales, there is *high confidence* that the WAfriM strengthened during the early-to-mid Holocene in response to orbitally-forced enhancement of summer warming in the Northern Hemisphere.

8.3.2.4.4 North American Monsoon

Since AR5, there have been updates on the observed long-term variations and changes in the North American monsoon (NAmerM). During the Last Glacial Maximum (21,000-19,000 years ago), the NAmerM was substantially weaker due to cold, dry mid-latitude air associated with the Laurentide Ice Sheet (Bhattacharya et al., 2017b, 2018). The NAmerM strengthened until the mid-Holocene period, in response to ice sheet retreat and rising summer insolation, but probably did not exceed the strength of the modern system (*low confidence*), as indicated by model simulations (Metcalfe et al., 2015) and paleoclimatic reconstructions (Bhattacharya et al., 2018). Paleoclimatic evidence from proxy datasets and mid-Pliocene (PlioMIP1) simulations suggest a wetter southwestern United States during that warmer period (Haywood et al., 2013a; Pound et al., 2014; Ibarra et al., 2018) but it is not clear whether this is due to increases of precipitation

ACCEPTED VERSION SUBJECT TO FINAL EDITING

associated with the monsoon or occurring during the winter season.

During 1948-2010, trends of boreal summer precipitation amount were significantly positive over New Mexico and the core NAmerM region, but significantly negative over southwestern Mexico (Hoell et al., 2016). In addition, diverse datasets like CRU, CHIRPS and GPCP show significant decreases of precipitation in parts of the southwest United States and northwestern Mexico, including the NAmerM region (Ashfaq et al., 2020; Cavazos et al., 2020). Other studies suggest a strengthening of the NAmerM upper level anticyclone since the mid-1970s, with a more frequent northward location (Diem et al., 2013). Between 1910-2010, the number of precipitation events increased across the northern Chihuahuan desert, within the NAmerM domain, despite a decrease in their magnitude, and the length of extreme dry and wet periods also increased (Petrie et al., 2014).

An increase in intense rainfall and severe weather events has been observed in several locations, especially in southwestern Arizona since 1991, resulting from increases in atmospheric moisture content and instability; a change that has been confirmed by convective-permitting model simulations (Luong et al., 2017; Pascale et al., 2019). A dense network of 59 rain gauges located in southeastern Arizona suggests an intensification of monsoon sub-daily rainfall since the mid-1970s (Demaria et al., 2019), as expected by a stronger global warming signature for sub-daily rather than daily or monthly precipitation accumulation (Section 11.4). Section 10.4.2.3 provides further details on changes in precipitation in southwestern North America. Evidence from multiple reanalyses suggests that increases in NAmerM rainfall have contributed to the increasing trend of global monsoon precipitation (Lin et al., 2014) (see also 2.3.1.4.2). In addition, more frequent occurrence of earlier retreats of the NAmerM since 1979 is documented (Arias et al., 2012, 2015), in association with the positive phase of the Atlantic Multidecadal Variability (AMV) and a westward expansion of the North Atlantic Subtropical High (Li et al., 2011, 2012b).

Analyses from a 50-km resolution GCM indicate that the NAmerM response to CO_2 is very sensitive to SST biases, showing reductions in summer NAmerM precipitation with increased CO_2 when the SST biases are small (Pascale et al., 2017) in contrast to CMIP5 models (Cook and Seager, 2013; Maloney et al., 2014; Torres-Alavez et al., 2014; Hoell et al., 2016). The NAmerM has been shown to be also sensitive to SO_2 emissions (García-Martínez et al., 2020).

In summary, both paleoclimate evidence and observations indicate an intensification of the NAmerM in a warmer climate (*medium confidence*). The intensification recorded since about the 1970s has been partly driven by GHG emissions (*medium confidence*).

8.3.2.4.5 South American Monsoon

Since AR5, there has been improved understanding of changes in the South American monsoon (SAmerM) as evidenced from paleoclimate records, instrumental observations and climate model simulations. However, GCMs still exhibit difficulties in reproducing SAmerM precipitation amount (Rojas et al., 2016; D'Agostino et al., 2020a). Paleoclimate evidence suggests a relatively stronger SAmerM during the 1400-1600 period (Bird et al., 2011b; Vuille et al., 2012; Ledru et al., 2013; Apaéstegui et al., 2014; Novello et al., 2016; Wortham et al., 2017). Last millennium GCM simulations are able to reproduce stronger SAmerM during the 1400-1600 period in comparison with warmer epochs such as the 900-1100 period (Rojas et al., 2016) or the current warming period (Díaz and Vera, 2018). PMIP3/CMIP5 simulations indicate a consistent weaker SAmerM during the mid-Holocene (6000 years ago; see Cross-Chapter Box 2.1) in comparison to current conditions (Bird et al., 2011a; Mollier-Vogel et al., 2013; Prado et al., 2013a; D'Agostino et al., 2020a), thus favouring savannah/grassland-like vegetation (Smith and Mayle, 2018), in agreement with climate reconstructions from different proxies (Prado et al., 2013b). Signals of weak and strong SAmerM during mid-Holocene and LGM, respectively, are evident also in high-resolution long-term (> ~ 22000 years) rainfall reconstructions based on oxygen isotopes in speleothems from Brazil (Novello et al., 2017; Stríkis et al., 2018b; Campos et al., 2019).

Isotope records from caves in the central Peruvian Andes show that the late Holocene (< 3000 years b.p) was characterized by multidecadal and centennial-scale periods of significant decline in intensity of the SAmerM

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Bird et al., 2011a; Vuille et al., 2012). This could be partly due to a reduction in the zonal SST gradient of the Pacific Ocean, favouring El Niño-like conditions (Kanner et al., 2013). Other studies suggest increased SAmerM precipitation amount during the Late Holocene, in association with the expansion of the tropical forest (Smith and Mayle, 2018). Well-dated equilibrium lines of glaciers during the deglaciation suggest that the AMOC enhances Atlantic moisture sources and precipitation amount increase over the tropical and southern Andes (Beniston et al., 2018).

Observations during 1979-2014 suggest that poleward shifts in the South Atlantic Convergence Zone (SACZ) noted in recent decades (Talento and Barreiro, 2018; Zilli et al., 2019), are associated with precipitation amount decrease along the equatorward margin and increase along the poleward margin of the convergenze zone (Zilli et al., 2019). Several observational studies identified delayed onsets of the SAmerM after 1978 related to longer dry seasons in the southern Amazon (Fu et al., 2013; Yin et al., 2014; Arias et al., 2015; Debortoli et al., 2015; Arvor et al., 2017; Giráldez et al., 2020; Haghtalab et al., 2020; Correa et al., 2021). In contrast, other studies indicate a trend toward earlier onsets of the SAmerM (Jones and Carvalho, 2013). These discrepancies are explained by the methodology used and the domain considered for the SAmerM, confirming the occurrence of delayed onsets of the SAmerM since 1978 (Correa et al., 2021). CMIP5 simulations show trends toward delayed onsets of the SAmerM in association with anthropogenic forcing, although the simulated trends underestimate the observed trends (Fu et al., 2013). Total rainfall reductions are observed in the southern Amazon during September-October-November after 1978 (Fu et al., 2013; Bonini et al., 2014; Debortoli et al., 2015, 2016; Espinoza et al., 2019), consistent with reductions in river discharge in the region (Molina-Carpio et al., 2017; Espinoza et al., 2019; Heerspink et al., 2020).

Significant increases in precipitation have been observed over southeastern Brazil during 1902-2005 while non-significant decreases have been found over central Brazil (Vera and Díaz, 2015). In Bolivia, increases were observed during 1965-1984, while reductions have occurred since then (Seiler et al., 2013). However, the Peruvian Amazon does not reveal significant changes in mean rainfall during 1965–2007 (Lavado et al., 2013; Ronchail et al., 2018). Historical simulations from CMIP5 ensembles adequately capture the observed summer precipitation amount over central and southeastern Brazil, thereby providing *high confidence* in interpreting the observed variability of SAmerM for the period 1960-1999 (Gulizia and Camilloni, 2015; Pascale et al., 2019). Also, CMIP5 simulations indicate that the anthropogenic forcing associated with increased GHG emissions is necessary to explain the positive trends in upper-troposphere zonal winds observed over the South American Altiplano (Vera et al., 2019). However, the detection of anthropogenically-induced signals for precipitation is still ambiguous in monsoon regions, like the SAmerM (Hoegh-Guldberg et al., 2019).

In summary, there is *high confidence* that the SAmerM onset has been delayed since the late 1970s. This is reproduced by CMIP5 simulations that consider anthropogenic forcing. There is also *high confidence* that precipitation during the dry-to-wet transition season has been reduced over the southern Amazon. Paleoclimate reconstructions and simulations suggest a weaker SAmerM during warmer epochs such as the Mid-Holocene or the 900-1100 period, and stronger monsoon during colder epochs such as the LGM or the 1400-1600 period (*high confidence*).

8.3.2.4.6 Australian and Maritime Continent Monsoon

Since AR5, several studies have examined observed variability and changes in the Australian and Maritime Continent Monsoon (AusMCM) using paleoclimate records, instrumental observations and modeling studies (Denniston et al., 2016; Zhang and Moise, 2016). Paleoclimate reconstructions and modelling indicate that the Indo–Australian monsoon may vary in or out of phase with the EAsiaM, depending on whether there is a meridional displacement or expansion of the tropical rainfall belt (Ayliffe et al., 2013; Denniston et al., 2016). For instance, mid-Holocene simulations suggest that the AusMCM weakens and contracts due to a decreased net energy input and a weaker dynamic component (D'Agostino et al., 2020a).

Rainfall increases have been observed over northern Australia since the 1950s, with most of the increases occurring in the north-west (Dey et al., 2018, 2019b; Dai, 2021) and decreases observed in the north-east (Li et al., 2012a) since the 1970s. There is also a trend towards more intense convective rainfall from

ACCEPTED VERSION SUBJECT TO FINAL EDITING

thunderstorms over northern Australia (Dowdy, 2020). There is no consensus on the cause of the observed Australian monsoon rainfall trends, with some studies suggesting changes are due to altered circulation driving increased moisture transport or increased frequency of the wettest synoptic regimes (Catto et al., 2012; Clark et al., 2018). Other studies find that model simulations that include anthopogenic aerosols (Rotstayn et al., 2012; Dey et al., 2018) are better able to capture observed Australian monsoon rainfall trends than simulations with natural or GHG forcing only (Knutson and Zeng et al., 2018).

The Maritime Continent (MC) experiences the influence of both the Asian and the Australian monsoons, with rainfall peaking during boreal winter/austral summer (Robertson et al., 2011). Reductions in land rainfall and marine cloudiness over the MC and weakening of surface moisture flux convergence have been observed in the period 1950-1999 (Tokinaga et al., 2012; Yoden et al., 2017). These trends are indicative of a slowdown of the Walker Circulation, with positive sea level pressure trends over the MC and negative trends over the central equatorial Pacific (Tokinaga et al., 2012). More recently (1981-2014), a trend of increasing annual rainfall over large areas of the MC has been identified (Hassim and Timbal, 2019). Given the large variability in MC rainfall on interannual time scales, the choice of time period may influence the calculated rainfall trend (Hassim and Timbal, 2019).

During 1951-2007 daily rainfall extremes did not increase over the MC, in contrast to the rest of Southeast Asia (Villafuerte et al., 2015) (see Section 11.4.2). Rainfall extremes in Indonesia increased in austral summer, as evidenced from station weather observations for the period 1983-2012 (Supari et al., 2018).

In summary, notable rainfall increases have been observed in parts of northern Australia since the 1970s, although there is *low confidence* in the human contribution to these changes. Rainfall changes have been observed over the MC region but there is *low confidence* in the identification of trends because of large variability at interannual timescales.

8.3.2.5 Tropical cyclones

AR5 assessed *low confidence* in centennial changes in tropical cyclone activity globally, and in the attribution of observed changes in TCs to anthropogenic forcing. Since AR5, there has been considerable progress in understanding the observed changes of TCs and an overall improved knowledge of the sensitivity of TCs to both GHG and aerosol forcing (Knutson et al., 2019; Sobel et al., 2019).

There is *medium confidence* that anthropogenic forcing has contributed to observed heavy rainfall events over the United States associated with TCs (Kunkel et al., 2012) and other regions with sufficient data coverage (Bindoff et al., 2013) (see also Section 11.7.1.2). There has been increased frequency of TC heavy-rainfall events over several areas in the United States since the late 19th century that is greater than what would be expected solely from changes in U.S. landfall frequency, suggesting the increasing role of TCs have in causing heavy-rainfall events (Kunkel et al., 2010). For example, there is evidence for an anthropogenic contribution to the extreme rainfall of Hurricane Harvey in 2017 (Emanuel, 2017; Risser and Wehner, 2017; Van Oldenborgh et al., 2017; Trenberth et al., 2018; Wang et al., 2018c).

While TCs cause extreme local rainfall and flooding, they can be also an important contributor to annual precipitation and regional fresh water resources (Hristova-Veleva et al., 2020). Transport of moisture by TCs is an important contributor for precipitation over the coastal areas of East Asia mostly from July through October, with the TC rainfall accounting for nearly 10% to 30% of the total rainfall in the region (Guo et al., 2017b). Local TC rainfall totals depend on rain-rate and translation speed (the speed of TC movement along the storm track) with slow TCs such as Hurricane Harvey (2017), providing a clear example of the effect of slow translation speed on local rainfall accumulation, with urbanization exacerbating the storm total rainfall and flooding (Zhang et al., 2018d) (see Section 11.7.1).

In addition to evidence that rain-rates have increased, there is evidence that TC translation speed has slowed globally (Kossin, 2018) thus amplifying thermodynamic intensification of rainfall and may be linked to anthropogenic forcing (Gutmann et al., 2018). This is *limited evidence* however, so there is *medium confidence*

ACCEPTED VERSION SUBJECT TO FINAL EDITING

of a detectable change in TC translation speed over the US. Since the 1900s, and there is *low confidence* for a global signal because of *limited agreement* among models and due to data heterogeneity. However, the slowdown is consistent with theoretical and modelling studies that indicate a general weakening of the tropical circulation with warming that reduces the speed of the TC system (Chauvin et al., 2017), though there is *limited* observational *evidence* (Sections 8.2.3.5, 11.7.1). Despite growing evidence that TC rainfall measures indicating increases, in general there is *low confidence* that a global anthropogenically forced trend in TC precipitation has been detected (Knutson et al., 2019), partly due to observational data limitations (e.g., Lau and Zhou, 2012).

In summary, there is *low confidence* of an observed increase in TC precipitation intensity due to observing system limitations. However, robust physical understanding (Section 8.2.3.2) and detailed singular event attribution studies provide evidence that tropical cyclone rainfall has increased with a warming climate (*high confidence*, Section 11.7.1.4).

8.3.2.6 Stationary waves

Stationary waves are planetary-scale waves that are approximately stable (stationary) in terms of geographic position, as opposed to propogating planetary waves, and are important both as part of the climatological general circulation and seasonal and shorter-term anomalies. They are related to surface features including land-ocean contrasts and major mountain ranges, as well as atmospheric features including the jet stream, storm tracks, and blocking, which are considered separately in the following sections. While zonal mean changes in P-E are dominated by thermodynamic effects (Section 8.2.2.1), changes in stationary waves are of key importance in understanding zonal asymmetries in the water cycle response to global warming (Wills and Schneider, 2015; Wills et al., 2019). AR5 did not explicitly assess stationary waves, but noted changes in related circulation features such as a *likely* poleward shift of the Northern Hemisphere storm tracks and an increase in frequency and eastward shift in North Atlantic blocking anticyclones, although there was *low confidence* in the global assessment of blocking.

Since AR5, several studies have demonstrated a link between stationary wave amplitude and wet and dry extremes in several different regions of the Northern Hemisphere (Liu et al., 2012; Coumou et al., 2014; Screen and Simmonds, 2014; Yuan et al., 2015) with changes in moisture transport playing an important role (Yuan et al., 2015). A 'resonance mechanism' has been proposed for an increasing amplitude of stationary waves (Petoukhov et al., 2013, 2016; Coumou et al., 2014; Kornhuber et al., 2017) and several studies have linked increasing amplitude of stationary waves to Arctic warming (Francis and Vavrus, 2012, 2015; Liu et al., 2012; Tang et al., 2014) as well as to global warming (Mann et al., 2017). However, other studies have not identified an increase in stationary wave amplitude (Barnes, 2013; Screen and Simmonds, 2013b, 2013a)

There has been considerable work on linkages (teleconnections) between Arctic warming and the mid-latitude circulation (see also Cross-Chapter Box 10.1). The limited amount of research on Southern Hemisphere stationary waves suggests changes in high latitude, mid-tropospheric stationary waves which influence Antarctic precipitation (Turner et al., 2017) and changes in stratospheric stationary waves that are associated with ozone depletion rather than increases in GHGs (Wang et al., 2013a). The observed climatology of Northern Hemisphere winter stationary waves is well-represented in the CMIP5 multi-model mean (Wills et al., 2019) but individual models have important deficiencies in reproducing stationary wave variability (Lee and Black, 2013). In the Southern Hemipshere, the observed climatology of stationary waves in CMIP5 models has considerable bias in both phase and amplitude (Garfinkel et al., 2020). A comprehensive assessment is not yet available for CMIP6 models.

In summary, there is *low confidence* in strengthened wintertime stationary wave activity over the North Atlantic, associated with increased poleward moisture fluxes east of North America There is *medium confidence* in a recent amplification of the Northern Hemisphere stationary waves in summer, but no formal attribution to anthropogenic climate change.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

8.3.2.7 *Atmospheric blocking*

Atmospheric blocking refers to persistent, semi-stationary weather patterns characterized by a high-pressure (anticyclonic) anomaly that interrupts the westerly flow in the mid-latitudes of both hemispheres. By redirecting the pathways of mid-latitude cyclones, blocking can affect the water cycle and lead to negative precipitation anomalies in the region of the blocking anticyclone and positive anomalies in the surrounding areas (Sousa et al., 2017). In this way, blocking can also be associated with extreme events such as heavy precipitation (Lenggenhager et al., 2018), drought (Schubert et al., 2014) and heatwaves (Miralles et al., 2014a). AR5 reported *low confidence* in global-scale changes in blocking, due to methodological differences between studies.

Currently no consensus exists on observed trends in blocking during 1979-2013. (Horton et al., 2015) identified increasing trends in anticyclonic circulation regimes based on geopotential height fields in the mid troposphere, which may be partly related to the tropospheric warming itself and thus not represent real changes in the statistics of weather (Horton et al., 2015; Woollings et al., 2018). Hanna et al. (2018) and (Davini and D'Andrea, 2020) reported a significant increase in the frequency of summertime blocking over Greenland. A weakening of the zonal wind, eddy kinetic energy and amplitude of Rossby waves in summer in the Northern Hemisphere (Coumou et al., 2015, Kornhuber et al., 2017, 2019) and an increased 'waviness' of the jet stream associated with Arctic warming (Francis and Vavrus, 2015; Pfahl et al., 2015; Luo et al., 2019) have also been identified, which may be linked to increased blocking.

In contrast, it has been shown that observed trends in blocking are sensitive the choice of the blocking index, and that there is a large internal variability that complicates the detection of forced trends (Barnes et al., 2014; Cattiaux et al., 2016; Woollings et al., 2018), compromising the attribution of any observed changes in blocking. Many climate models still underestimate the occurrence of blocking, at least in winter over northeastern Atlantic and Europe (Dunn-Sigouin and Son, 2013), which leads to caution in the interpretation of their results for these regions. However, over the Pacific Ocean there have been large improvements in the simulation of blocking for the last 20 years (Davini & D'Andrea, 2016; Patterson et al., 2019). In the Southern Hemisphere, increases in blocking frequency have occurred in the South Atlantic in austral summer (Dennison et al., 2016) and in the southern Indian Ocean in austral spring (Schemm, 2018). A reduced blocking frequency has been found over the southwestern Pacific in austral spring (Schemm, 2018) (see also sections 2.3.1.4.3 and 3.4.1.3.3).

In summary, no robust trend in atmospheric blocking has been detected in modern reanalyses and in CMIP6 historical simulations (*medium confidence*). The lack of trend is explained by strong internal variability and/or the competing effects of low-level Arctic amplification and upper-level tropical amplification of the equator-to-pole temperature gradient (*medium confidence*).

8.3.2.8 *Extratropical cyclones, storm tracks and atmospheric rivers*

8.3.2.8.1 *Extratropical cyclones and storm tracks*

AR5 indicated *low confidence* in long-term changes in the intensity of extratropical cyclones (ETC) over the 20th century derived from centennial reanalyses and storminess proxies based upon sea level pressure. This was confirmed by the SREX assessment that the main Northern Hemisphere and Southern Hemisphere extratropical storm-tracks *likely* experienced a poleward shift during the last 50 years (Seneviratne et al., 2012) with *low confidence*, and inconsistencies within reanalysis datasets remain.

Since AR5 there has been considerable progress in quantifying storm-track activity using multiple reanalysis products and different methodologies (Hodges et al., 2011; Neu et al., 2013; Tilinina et al., 2013; Wang et al., 2016b). Over the Northern Hemisphere increases in the total number of cyclones from 1979 show a large spread of trends across different estimates (Neu et al., 2013; Li et al., 2016b; Grieger et al., 2018) (see also Section 2.3.1.4.3) resulting in *low confidence* in any clear increase of in the total number of cyclones. However, starting from the early 1990s, most reanalyses show increases in the total cyclone number by about

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2-5% per decade (Figure 8.12). Increasing trends in the total number of cyclones are dominated by the increase in the number of shallow and moderate cyclones (which are more dependent on the datasets and identification mentods used) than with decreasing number of deep cyclones since the early 1990s (Tilinina et al., 2013; Chang, 2018). In the Southern Hemisphere the variability of the total number of cyclones is characterized by strong interdecadal variability preventing a clear assessment of trends. However, in contrast to the Northern Hemisphere,there is a significant increasing trend in the number of deep cyclones (~10% over 1979-2018) in ERA5, ERA-Interim, JRA55 and MERRA, and in the CFSR dataset after 2000 (Reboita et al., 2015; Wang et al., 2016b) (Figure 8.12).

Changes in the number of deep storms, which are often associated with heavier precipitiation over the North Atlantic and North Pacific, exhibit strong seasonal differences and decadal variability (Colle et al., 2015; Chang et al., 2016; Matthews et al., 2016, Priestley et al., 2020). An increase in the number of summer cyclones over the Atlantic-European sector (Tilinina et al., 2013) is consistent with the increase in the strength of the strongest fronts over Europe (Schemm et al., 2018). (Chang et al., 2016) reported a decrease in the number of strong summer storms in the latitudinal band 40º-75ºN over the last decades, however, the assessment of seasonal trends in the Atlantic-European sector is complicated by the choice of region, attribution of tracks to the region selected, and thresholds used to identify trajectories, leading to *low confidence* on regional seasonal trends. For the Southern Hemisphere, Grieger et al. (2018) reported growing number of cyclones over sub-Antarctic region in the austral-summer during 1979-2010, while statistically significant trends were absent during the austral winter.

[START FIGURE 8.12 HERE]

Figure 8.12: Annual anomalies (with respect to the reference period 1979-2018) of the total number of extratropical cyclones (a, c) and of the number of deep cyclones (<980hPa) (b, d) over the Northern (a, b) and the Southern (c, d) Hemispheres in different reanalyses (shown in colours in the legend). Note different vertical scales for panels (a), (b) and (c), (d). Thin lines indicate annual anomalies and bold lines indicate 5-yr running averages. (e), (f) The number of reanalyses (out of five) simultaneously indicating statistically significant (90% level) linear trends of the same sign during 1979–2018 for JFM over the Northern Hemisphere (e) and over the Southern Hemisphere (f). Updated from (Tilinina et al., 2013). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.12 HERE]

Analysis of storm-track activity over longer periods suffers from uncertainties associated with changing data assimilation and observations before and during the satellite era, resulting in inhomogeneities and discontinuities in centennial reanalyses (Krueger et al., 2013, Chang and Yau, 2016; Wang et al., 2013, 2016, Varino et al., 2019a). (Feser et al., 2015) reviewed multiple storm track records for the Atlantic-European sector and demonstrated growing storm activity north of 55°N from the 1970s to the mid 1990s with declining trend thereafter, sugesting strong interdecadal variability in storm track activity. This was also confirmed by (Krueger et al., 2019) from the analysis of geostrophic winds derived from sea level pressure gradients.

Poleward deflection of mostly oceanic winter storm tracks since 1979 was reported in both the North Atlantic and North Pacific (Tilinina et al., 2013; Wang et al., 2017b). This large-scale tendency has regional variations and may be seasonally dependent. Wise and Dannenberg (2017) reported a southward shift in the east Pacific storm-track from the 1950s to mid-1980s followed by northward deflection in the later decades. (King et al., 2019) resported an association of Atlantic storm track migrations with SSW events with Central and South European preciptiation anomalies. Over centennial time-scales, Gan and Wu (2014) reported an intensification of stormtracks in the poleward and downstream regions of the North Pacific and North Atlantic upper troposphere using 20CR reanalysis. Poleward migration of the Southern Hemisphere storm-tracks (Grise et al., 2014; Wang et al., 2016b; Dowdy et al., 2019) was identified during the austral summer and is closely associated with cyclone-associated frontal activity (Solman and Orlanski, 2014, 2016) and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

cloud cover (Bender et al., 2012; Norris et al., 2016).

The representation of ETCs in both climate models and reanalyses is resolution-dependent, hence changes must be assessed with caution (Section 3.3.3.3). In particular, CMIP5 models show a systematic underestimation of the intensity of ETCs (Zappa et al., 2014), a feature that is partially related to their relatively coarse resolution or other possible deficiencies such as an excess of dissipation (Chang et al., 2013). The best representation of ETCs and their intensity in the North Atlantic are provided by relatively high horizontal resolution CMIP5 models (Zappa et al., 2014). Using a single high-resolution climate model, (Hawcroft et al., 2016) showed that precipitation amount associated with ETCs was generally well simulated though with too much precipitation during the strongest ECTs compared with observed estimations.

In summary, there is *low confidence* in recent changes in the total number of extra-tropical cyclones over both hemispheres. It is *as likely as not* that the number of deep cyclones over the Northern Hemisphere has decreased after 1979 and it is *likely* that the number of deep extra-tropical cyclones increased over the same period in the Southern Hemisphere. It is *likely* that extra-tropical cyclone activity in the Southern Hemisphere has intensified during austral summer with no significant changes in austral winter. There is *medium confidence* that boreal-winter storm tracks during the last decades experienced poleward shifts over the Northern and Southern Hemisphere oceans. There is *low confidence* of changes in extra-tropical cyclone activity prior 1979 due to inhomogeneities in the intrumental records and modern reanalyses.

8.3.2.8.2 Atmospheric rivers

Atmospheric rivers (ARs) are long, narrow (up to a few hundred km wide), shallow (up to few km deep) and transient corridors of strong horizontal water vapour transport that are typically associated with a low-level jet stream ahead of the cold front of an extratropical cyclone (Ralph et al., 2018). Atmospheric rviers were not assessed in AR5. ARs are associated with atmospheric moisture transport from the tropics to the mid and high latitudes (Zhu and Newell, 1998), although the drivers of moisture transport relative to the different airstreams within extratropical cyclones remains a subject of current study (Dacre et al., 2019). While much previous research has focused on the west coast of North America, ARs occur throughout extratropical and polar regions (e.g., Guan and Waliser, 2015) and are often associated with locally-heavy precipitation, including a substantial fraction of all midlatitude extreme precipitation events (e.g., Waliser and Guan, 2017). ARs also affect East Asia strongly during the period from late spring to summer (Kamae et al., 2017). ARs can be related to warming/melt events trough the intrusions of warm and moist air in Antarctica, Greenland and New Zealand (Bozkurt et al., 2018; Mattingly et al., 2018; Little et al., 2019), contributing about 45-60% of total annual precipitation in subtropical South America (Viale et al., 2018). They also transport moisture from South America to the western and central South Atlantic, feeding the ARs that reach the west coast of South Africa (Ramos et al., 2019). However, the estimation of precipitation rate from ARs can have large uncertainties, especially as ARs hit topographically complex coastal regions (Behrangi et al., 2016), which can cause complexities in quantifying AR-related precipitation.

Analysis of observed trends in the characteristics of ARs has been limited. (Gershunov et al., 2017) and (Sharma and Déry, 2019) have shown a rising trend in land-falling AR activity over the west coast of North American since 1948. (Gonzales et al., 2019) have also documented a seasonally-asymmetric warming of ARs affecting the United States West Coast since 1980, which has hydrological implications for the timing and magnitude of regional runoff. Longer-term paleoclimate analysis of ARs is even more limited, although Lora et al. (2017) reported that in the last glacial maximum, AR landfalls over the North America west coast were shifted southward compared to the present conditions.

In summary, it is *likely* that there was an increasing trend in the AR activity in the eastern North Pacific since the mid-20th century. However, there is *low confidence* in the magnitude of this trend and no formal attribution, although such an increase in activity is consistent with the expected and observed increase in precipitable water associated with human-induced global warming.

8.3.2.9 Modes of climate variability and regional teleconnections

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Following on from the assessment in Chapters 2 and 3, this section considers changes in modes of variability at seasonal to interannual timescales in terms of their implications on recent water cycle changes. These modes are described in details in Technical Annex IV.

8.3.2.9.1 Tropical modes

The amplitude of the El Niño–Southern Oscillation (ENSO, Section AIV.2.3) variability has increased since 1950 (Section 2.4.2) but there is no clear evidence of human influence (Sections 2.4.2 and 3.7.3).

ENSO influences precipitation and evaporation dynamics, river flow and flooding at a global scale (see also Figure 3.37) (Ward et al., 2014, 2016; Martens et al., 2018). Reconstruction (1804-2005) of Thailand's Chao Praya River peak season streamflow displays a strong correlation with ENSO (Xu et al., 2019). Based on water storage estimates from 2002 to 2015, drought conditions over the Yangtze River basin followed La Niña events and flood conditions followed El Niño events (Zhang et al., 2015b). Strong correlation between ENSO and terrestrial water storage has been identified mostly in the subtropics but with diverse intensities and timelags depending on the region (Ni et al., 2018). The likelihood of increased/decreased flood hazard during ENSO events has a complex spatial pattern with large uncertainties (Emerton et al., 2017).

Tropical SSTs and associated global circulation may increase rainfall in West Africa, as observed in some years during 1950-2015, despite the presence of El Niño (Pomposi et al., 2020). During an El Niño summer, equatorial convective systems and the associated Walker circulation tend to shift eastward, leading to decreases in Indian summer monsoon rainfall (Li and Ting, 2015; Roy et al., 2019) (Lee and Tamas accepted). This teleconnection is modulated by Indian Ocean variability (Terray et al., 2021), as observed during the extreme positive IOD event in 2019 (Ratna et al., 2021). Since the end of the 19th century, synchronous hydroclimate changes (*medium confidence*) have been identified over south eastern Australia and South Africa (Gergis and Henley, 2017) modulated by ENSO, as well as other regional fluctuations like the Botswana High over Southern Africa (Driver and Reason, 2017). Over southern South America, the ENSO influence on precipitation (Cai et al., 2020; Poveda et al., 2020) interacts with the influence of SAM (Pedron et al., 2017), exhibiting large multi-decadal variations because of changes in the correlation between the two large-scale modes (Vera and Osman, 2018). Other processes underlying ENSO teleconnections of relevance for water cycle changes include water vapour and moisture transports, like over the Middle East (Sandeep and Ajayamohan, 2018), southeastern China (Yang et al., 2018c), or central Asia (Chen et al., 2018b), southeastern South America (Martín-Gómez and Barreiro, 2016; Martin-Gomez et al., 2016), Australia (Rathore et al., 2020) and southern United States (Okumura et al., 2017).

There is no evidence of trend in the Indian Ocean Dipole (IOD, Section AIV.2.4) mode and associated anthropogenic forcing (Sections 2.4.3 and 3.7.4). AR5 concluded that the IOD is *likely* to remain active, affecting climate extremes in Australia, Indonesia and east Africa. Since the AR5, IOD teleconnections have been identified extending further to the Middle East (Chandran et al., 2016), to the Yangtze river (Xiao et al., 2015), where in boreal summer and autumn positive IOD events tend to increase the precipitation in the southeastern and central part of the basin, and to the southern Africa extreme wet seasons (Hoell and Cheng, 2018). During the last millenium, the combined effect of a positive IOD and El Niño conditions have caused severe droughts over Australia (Abram et al., 2020). In the satellited period, it is found more effective in inducing significant decrease of rainfall over Indonesia, with the opposite occurring for negative IOD events (As-syakur et al., 2014; Nur'utami and Hidayat, 2016; Pan et al., 2018). Similarly, over the Ganges and Brahmaputra river basins major droughts have been recorded during co-occurring El Niño and positive IOD, while floods occurred during La Nina and negative IOD conditions (Pervez and Henebry, 2015). Over equatorial East Africa the IOD affects the short rain season (*medium confidence*) exacerbating flooding and inundations independently of ENSO (Behera et al., 2005; Conway et al., 2005; Ummenhofer et al., 2009; Hirons and Turner, 2018). Extreme conditions, like 2019 Australian bushfires and African flooding, have been associated with strong positive IOD conditions (Cai et al., 2021).

Intraseasonal variability, like the Madden Julian Oscillation (MJO, Section AIV.2.8) and the Boreal Summer Intraseasonal Oscillation (BSISO), are highly relevant to the water cycle (Maloney and Hartmann, 2000; Lee

ACCEPTED VERSION SUBJECT TO FINAL EDITING

et al., 2013; Yoshida et al., 2014; Nakano et al., 2015). Since AR5, studies on MJO teleconnections within the tropics and from the tropics to higher latitudes have continued (Guan et al., 2012; Mundhenk et al., 2018; Tseng et al., 2019; Aberson and Kaplan, 2020; Finney et al., 2020b; Fowler and Pritchard, 2020; Fromang and Rivière, 2020).

The strength and frequency of the MJO have increased over the past century (*medium confidence*) (Oliver and Thompson, 2012; Maloney et al., 2019; Cui et al., 2020) because of global warming (Arnold et al., 2015; Carlson and Caballero, 2016; Wolding et al., 2017; Maloney et al., 2019). A 20th century reconstruction suggests a 13% increase of the MJO amplitude (Oliver and Thompson, 2012), with differences in seasonal variability (Tao et al., 2015; Wang et al., 2020e). However, up to half of changes recorded during the second half of the 20th century could be due to internal variability (Schubert et al., 2013). Other observed changes in MJO characteristics include a decrease (by 3-4 days) in the residence time over the Indian Ocean but an increase (by 5-6 days) over the Indo-Pacific and Maritime Continent sectors (Roxy et al., 2019).

Consequences of these changes are increased rainfall over Southeast Asia, northern Australia, southwest Africa and the Amazon, and drying over the west coast of the United States and Equador (Roxy et al., 2019). During the austral summer, air-sea interactions and location of the MJO active phase are important to modulate the strength of the rainfall response in the South Atlantic Convergence Zone (Shimizu and Ambrizzi, 2016; Alvarez et al., 2017), including its southward shift (Barreiro et al., 2019). In the austral winter, the intraseasonal variability is mostly influential over regions of the Amazon Basin (Mayta et al., 2019). Some MJO phases are particularly effective in conjuction with tropical cyclones in enhancing westerly moisture fluxes toward east Africa (Finney et al., 2020b).

Simulated changes in MJO precipitation amplitude are extremely sensitive to the pattern of SST warming (Takahashi et al., 2011; Maloney and Xie, 2013; Arnold et al., 2015) and ocean-atmosphere coupling (DeMott et al., 2019; Klingaman and Demott, 2020). In agreement with results from previous model generations, most CMIP5 models still underestimate MJO amplitude, and struggle to generate a coherent eastward propagation of precipitation and wind (Hung et al., 2013; Jiang et al., 2015; Ahn et al., 2017), affecting regional surface climate in the tropics and extra-tropics. In addition, most CMIP5 models simulate an MJO that propagates faster compared with observations, with a poorly represented intra-seasonal precipitation variability (Ahn et al., 2017). Over the Indian Ocean, the propagation speed of convection in some CMIP5 models tends to be slower than observed due to a strong persistence of equatorial precipitation (Hung et al., 2013; Jiang et al., 2015). Among other processes, improving the moisture-convection coupling, the representation of moist convection, the interaction between lower tropospheric heating and boundary layer convergence, and the topography of the Maritime Continent improve simulations of the MJO (Ahn et al., 2017, 2020a; Kim and Maloney, 2017; Yang and Wang, 2019; Tan et al., 2020a; Yang et al., 2020b). In fact, CMIP6 models reproduce the amplitude and propagation of the MJO better than CMIP5 models due to increased horizontal moisture advection over the Maritime Continent (Ahn et al., 2020b). Despite the diverse theories of MJO evolution and processes that have been developed since its discovery, a better understanding of its dynamics is still needed (Jiang et al., 2020; Zhang et al., 2020). Furthermore, metrics based on dynamical processes are needed to assess model simulations of these events (Stechmann and Hottovy, 2017; Wang et al., 2018a) as well as related teleconnections (Wang et al., 2020c).

In summary, multiple water cycle changes related to ENSO and IOD teleconnections have been observed across the 20th century (*high confidence*), mostly dominated by interannual to multi-decadal variations. The MJO amplitude has increased in the second half of the 20th century partly because of anthropogenic global warming (*medium confidence*) altering regional precipitation signals.

8.3.2.9.2 Extra-tropical modes

A positive trend has been observed in the Northern Annular Mode (NAM, Section AIV.2.1) in the second half of the 20th century, which partially reversed since the 1990s (Section 2.4.5.1), but the detection and attribution of these changes remain difficult (Section 3.7.1). The linkages of the NAM with weather and climate extremes in the northern extra-tropics are still unclear in models and observations (Vihma, 2014; Overland et al., 2016; Screen et al., 2018). However, robust links are identified between precipitation trends

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and variability in Europe and the phases of the Atlantic component of the NAM, i.e. the NAO (Moore et al., 2013; Comas-Bru and McDermott, 2014). Reduced winter precipitation is well correlated with the NAO over Southern Europe and Mediterranean countries (Kalimeris et al., 2017; Corona et al., 2018; Vazifehkhah and Kahya, 2018; Neves et al., 2019). NAO teleconnections in those regions include influences on groundwater and streamflow (Zamrane et al., 2016; Massei et al., 2017; Jemai et al., 2018). Remote teleconnections of the NAO have been identified over Northern China, the Yangtze River valley and India (Jin and Guan, 2017; Di Capua et al., 2020). The summer phase of the NAO is significantly correlated with variations in summer rainfall in East China, with the thermal forcing of the Tibetan Plateau providing a link to this Eurasian teleconnection (Wang et al., 2018f).

In the Southern Hemisphere, an observed positive trend is identified in the strength of the Southern Annular Mode (SAM, Section AIV.2.2) since 1950, especially in austral summer (*high confidence*, Section 2.4.1.2). While stratospheric ozone depletion and GHG increases largely contributed to this change, climate models still have trouble simulating the SAM and its response to ozone and GHGs (Section 3.7.2). Shifts in the southwesterly winds (Fletcher et al., 2018) and the expansion of the Southern Hemisphere Hadley cell (Kang and Polvani, 2011; Nguyen et al., 2018a) influence SAM-related rainfall anomalies in in southern South America and southern Australia during the austral spring–summer. Over New Zealand, large-scale SLP and zonal wind patterns associated with SAM phases modulate regional river flow (Li and McGregor, 2017). The SAM also influences precipitation and water vapour changes over Antarctica via moisture fluxes (Marshall et al., 2017; Oshima and Yamazaki, 2017; Grieger et al., 2018) but CMIP5 models are limted in their ability to simulate these regional teleconnections (Marshall and Bracegirdle, 2015; Palerme et al., 2017). SAM and its interaction with other large-scale modes of climate variability, like ENSO (Fogt et al., 2011) and the Indian Ocean Dipole (Hoell et al., 2017a), are responsible for fluctuations in Southern African rainfall (Nash, 2017) and southern South America (Gergis and Henley, 2017). In May, the SAM can trigger a southern Indian Ocean dipole SSTA favoring more or less precipitation over the Indian sub-continent and adjacent areas (Dou et al., 2017), also affecting subsequent summer monsoon in the South China Sea (Liu et al., 2018d). Over South America, a positive SAM is associated with dry conditions (Holz et al., 2017) due to reduced frontal and orographic precipitation and weakening of moisture convergence. Regions particularly affected include Chile (Boisier et al., 2018) and the rivers of central Patagonia (Rivera et al., 2018).

In summary, while the attribution of 20th century variations of the NAM/NAO is still unclear, there is a strong relationship with precipitation changes over Europe and in the Mediterranean region (*high confidence*). SAM teleconnections are associated with changes in moisture transport and extend to South America, Australia and Antarctica *(high confidence)* with documented drying occurring as a result of the *very likely* human-induced SAM trend toward its positive phase observed from the 1970s until the 1990s (Section 3.7.2).

8.4 What are the projected water cycle changes?

We consider global and regional climate projections of the water cycle, assessing projected changes in each component of the water cycle (Section 8.4.1) and the global-scale and regional phenomena that directly impact it (Section 8.4.2).

8.4.1 Projected water cycle changes

Most projected changes in the water cycle are not expected to be uniform in space or time. They are driven by both dynamical and thermodynamical processes (Section 8.2) and have not necessarily emerged yet in the recent observational record (Section 8.3) as they are superimposed on substantial natural fluctuations in weather and climate. Therefore, projecting regional water cycle changes remains challenging. However, a number of physically understood responses can be evaluated using both CMIP5 and CMIP6 models, which are important for guiding decision making that anticipates, prepares for, and responds to water cycle changes. In this section, global maps of projected changes in water cycle variables are assessed using the WGI AR6 'simple method' (see Cross-Chapter Box Atlas1), which uses hatching to highlight where less

ACCEPTED VERSION SUBJECT TO FINAL EDITING

than 80% of the models agree on the sign of projected changes. This choice differs from Section 4.2.6 for a number of reasons. These include the weak signal-to-noise ratio of projected hydrological changes in low to medium emission scenarios, the sensitivity of their statistical significance to the baseline reference period, and the non-Gaussian distribution of many water cycle variables (see CCB Atlas.1 for more details on strengths and limitations of the hatching methods implemented within AR6).

8.4.1.1 Global water cycle intensity and P-E over land and oceans

As discussed in 8.3.1.1, the definition of global water cycle intensity varies from the simple metric of increases in global mean precipitation to broader joint considerations of water vapour and its transport, precipitation minus evaporation (P-E) rates and continental runoff (see Figure 8.1). AR5 determined that globally averaged precipitation is *virtually certain* to increase with temperature and that there is *high confidence* that the contrast of annual mean precipitation between dry and wet regions and seasons will increase over most of the globe as temperatures and moisture transports increase (Collins et al., 2013). AR5 also highlighted that continued ocean warming for a few decades after GHG forcing stabilizes or begins to decrease will also lead to further increases in global mean precipitation and evaporation.

In this Report, Chapter 4 provides an updated assessment of global annual precipitation (Section 4.3.1), finding that it is *very likely* that annual precipitation averaged over all land regions continuously increases as global surface temperatures increase in the 21st century (*high confidence*). CMIP6 projections for long-term changes in P-E (Figure 8.13) show that, for all scenarios, P-E increases over the tropics and high latitudes and decreases over the subtropics, resulting from a thermodynamically driven amplification of P-E patterns (Section 8.2.2.1). Both the intensity of changes and the spread among the models is larger for the higher emission scenarios. A less coherent latitudinal pattern and smaller magnitude of P-E changes over land reflect the complex influence of land-ocean warming contrast, atmospheric circulation change and vegetation feedbacks (Section 8.2.2.1). However, stronger atmospheric moisture transport, increases in precipitation and evaporation over global land and ocean and larger continental runoff that is in part fed by melting of glaciers characterises a more intense water cycle with global warming.

Global and global land mean water cycle changes from CMIP6 projections are shown in Table 8.1. Increases in global and continental precipitation, P-E and runoff in both the mid-term and long-term illustrate the future intensification of the water cycle, with the magnitude of change increasing with emission scenario. Consistent with AR5, CMIP6 simulations of global mean precipitation show a systematic multi-model mean increase of 1.6% to 2.9 % per 1°C warming (apparent hydrological sensitivity; Section 8.2.1) by 2081-2100 relative to present day across the new SSP scenarios (using global surface air temperature change from Table 4.1). It is well understood that rising concentrations of CO_2 drive a long-term increase in global precipitation with warming, but with the increase partly offset by rapid atmospheric adjustments to the direct atmospheric heating from radiative forcing agents (Section 8.2.1). The largest apparent hydrological sensitivity is found for SSP1-1.9, where the suppressing effects on precipitation from atmospheric heating by greenhouse gases rapidly reduced as their concentration falls. Additional warming due to reduced aerosol loadings under the SSP scenarios (Lund et al., 2019) further increases global precipitation (Rotstayn et al., 2013; Wu et al., 2013; Salzmann, 2016; Richardson et al., 2018b; Samset et al., 2018b; Westervelt et al., 2018), with particularly strong contributions from increased monsoon rainfall over East and South Asia (Levy et al., 2013; Westervelt et al., 2015; Dwyer and O'Gorman, 2017).

Over global land there is a small range in global mean multi-model mean precipitation increase across scenarios in the mid-term (2.6-4.0%), which widens (to 2.6-8.8%) in the long-term (Table 8.1). The long term projections are consistent with the Chapter 4 assessment that global annual precipitation over land is projected to increase on average by 2.4 [-0.2 to 4.7] % (*very likely* range) in the SSP1-1.9 low-emission scenario and by 8.3 [0.9 to 12.9] % in the SSP5-8.5 high-emission scenario by 2081–2100 relative to 1995–2014. Small differences in assessed model mean changes in Chapter 4, Table 4.2 result from a slightly different set of models considered for Table 8.1. Over land, P-E increases by ~2-3% in the mid-term (apart from SSP5-8.5 where increases are almost 5%) and ~1-12% in the long-term, determined by increased moisture transport from the ocean to land (Section 8.4.1.2). Runoff increases are larger and less certain due

ACCEPTED VERSION SUBJECT TO FINAL EDITING

to additional inputs from glacier melt and changes in groundwater storage (Section 8.4.1.7). Overall, precipitation and runoff are *very likely* to increase over the global land in all scenarios in the mid term and long term. P-E is *likely* to increase over global land in the mid and long term and *very likely* in SSP1-1.9, SSP3-7.0 and SSP5-8.5 pathways. The mid-term consistency in projections across scenarios is not apparent for precipitable water vapour, which increases over land by around 6-15% in the mid-term and 5-36% in the long-term across all scenarios. This implies that increases in extreme precipitation (closely related to atmospheric water vapour content; Section 8.2.3.2) are dependent on mitigation pathway, even in the mid-term (Section 11.4.5). Water vapour residence time (computed as the ratio of precipitable water vapour to precipitation from values in Table 8.1) increases from 8 days in the present to 9 days in mid-term and up to about 10 days in the long-term over land in SSP3-7.0, indicating a longer time to moisten the atmosphere between precipitation events. The CMIP6 projections are therefore consistent with an intensification but not acceleration of the global water cycle.

In summary, it is *virtually certain* that global water cycle intensity, considered in terms of global and continental mean precipitation, evaporation and runoff, will increase with continued global warming. Global annual precipitation over land is projected to increase on average by 2.4 [-0.2 to 4.7] % (*very likely* range) in the SSP1-1.9 low-emission scenario and by 8.3 [0.9 to 12.9] % in the SSP5-8.5 high-emission scenario by 2081–2100 relative to 1995–2014.

Figure 8.13: Zonal and annual mean projected long-term changes in the atmospheric water budget. Zonal and annual mean projected changes (mm/day) in P (precipitation, left column), E (evaporation, middle column), and P-E (right column) over both land and ocean areas (thick line) and over land only (dashed line) averaged across 36 to 38 CMIP6 models in the SSP1-2.6 (a,b), SSP2-4.5 (c,d) and SSP5-8.5 (e,f) scenario, respectively. Shading denotes confidence intervals estimated from the CMIP6 ensemble under a normal distribution hypothesis. Colour shading denotes changes over both land and ocean. Grey shading represents internal variability derived from the pre-industrial control simulations. All changes are estimated for 2081-2100 relative to the 1995-2014 base period. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.13 HERE]

8.4.1.2 Water vapour and its transport

Globally, AR5 assessed that by the end of the 21st century, the average quantity of water vapour in the atmosphere could increase by 5 to 25%, depending on emissions. AR5 assessed that increases in near-surface specific humidity over land are *very likely*, but that it was also *likely* that near-surface relative humidity would decrease over many land areas, although with only *medium confidence*. In terms of moisture transport, AR5 assessed that it was *likely* that moisture transport into the high latitudes would increase and that there was *high confidence* that, over the ocean, atmospheric moisture transport from the evaporative regions to the wet regions would increase.

CMIP6 climate models continue to project a steady increase in global mean column-integrated water vapour by around 6-13% by 2041-2060 and 5-32% by 2081-2100, depending on scenario (Table 8.1). This is consistent with projected atmospheric warming (Section 4.5.1.2) and the Clausius-Clapeyron relationship (Section 8.2.1) where every degree Celsius of warming is associated with a ~7% increase in atmospheric moisture in the lower atmospheric layers where most of the water vapour is concentrated. This increase sustains a positive feedback on anthropogenic global warming (Section 7.4.2.2). In contrast, the response of clouds is much more spatially heterogeneous, microphysically complex, and model-dependent so that the projected cloud feedbacks remain a key uncertainty for constraining climate sensitivity (Section 7.4.2.4).

CMIP6 models project an overall decrease in near-surface relative humidity over land, although with some regional and seasonal variations in their response (Fig. 4.26). Regional changes in near-surface humidity over land are dominated by thermodynamic processes and are primarily controlled by moisture transport from the warming ocean (Chadwick et al., 2016b). Increases in specific humidity lower than the thermodynamic rate are explained by greater warming over land than ocean and modulated by land-atmosphere feedbacks such as soil moisture and plant stomatal changes (Section 8.2.2.1) (Berg et al., 2017; Douville et al., 2020). This explains why climate models continue to project a contrasting response of near-surface relative humidity, with a slight and possibly overestimated increase over the oceans and a consistent but possibly underestimated decrease over land (Byrne and O'Gorman, 2016; Douville and Plazzotta, 2017; Zhang et al., 2018c).

While projections of water vapour are well understood due to the constraints of the Clausius-Clapeyron relationship, projections of water vapour transport are complicated regionally by the role of changes in the wind field, which is influenced by a wide variety of factors. Additionally, there has been relatively little general evaluation of moisture transport in models. In CMIP5 models, both the mean and variability of the vertically-integrated moisture transport is projected to increase, largely due to increases in water vapour (Lavers et al., 2015), with substantial regional differences (Levang and Schmitt, 2015). Single model studies have illustrated projected increases in low-altitude moisture transport into convergence regions (Allan et al., 2014) and from ocean to land (Zahn and Allan, 2013) that are consistent with present day trends. Increases in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

moisture transport have been linked to increases in large precipitation accumulations over land (Norris et al., 2019). Based on robust physics and supported by modelling studies, it is well understood that moisture transport increases into convergent parts of the atmospheric circulation such as storm systems, the tropical rain belt and high latitudes (Section 8.2.2.1), but changes in atmospheric circulation that are less well understood alter moisture transport regionally (Section 8.2.2.2). Therefore, given the limited examination of moisture transport in models, regional projections should be considered with caution. Changes in moisture transport specifically associated with monsoons, atmospheric rivers, and other specific circulation features are discussed further in the following sections.

In summary, there is *high confidence* in continued increases in global mean column integrated water vapour and near-surface specific humidity over land. There is *medium confidence* in region and season-dependent decreases in near-surface relative humidity over land, due to the complex physical processes involved. In general, there will be increases in moisture transport into storm systems, monsoons and high latitudes (*medium confidence*).

8.4.1.3 Precipitation amount, frequency and intensity

This section assesses projected changes in precipitation at regional scales. Note that changes in precipitation seasonality are assessed in Box 8.2 and that changes in regional monsoons are assessed in Section 8.4.2.4, where both circulation and rainfall are considered. Further assessments of regional projections of precipitation are presented in Chapters 10, 12 and the Atlas, while a comprehensive assessment of changes in precipitation extremes is provided in Chapter 11.

AR5 assessed that the contrast of mean precipitation amount between dry and wet regions and seasons is expected to increase over most of the globe as temperatures increase (*high confidence*), but with large regional variations. Precipitation over the high latitudes, equatorial Pacific Ocean, mid-latitude wet regions, and monsoon regions were assessed as *likely* to increase under the RCP8.5 scenario, and in many mid-latitude and subtropical dry regions as *likely* to decrease (AR5 Chapters 7, 12, and 14). Extreme precipitation over most mid-latitude land areas and wet tropical regions was assessed as *very likely* to become more intense and more frequent.

Geographical patterns of projected precipitation changes show substantial seasonal contrasts and regional differences, including over land (Figure 8.14; Figure 4.27). Projections for 2081-2100 under the SSP2-4.5 scenario suggest increased precipitation over the tropical oceans, northeastern Africa, the Arabian Peninsula, India, southeastern Asia and the Polar Regions while decreased precipitation is projected mainly over the subtropical regions (Section 4.5.1.4). Precipitation changes contrast regionally in the tropics with wetter wet seasons over South Asia, central Sahel and eastern Africa, but less precipitation over Amazonia and coastal West Africa (Section 8.4.2.4). These large-scale responses are associated with stronger moisture transports in a warmer climate that are modulated by the greater warming over land than ocean, atmospheric circulation responses and land surface feedbacks (Section 8.2.2). There is agreement across CMIP5 and CMIP6 modelling studies that precipitation increases in wet parts of the atmospheric circulation and decreases in dry parts (Liu and Allan, 2013; Kumar et al., 2015; Deng et al., 2020; Schurer et al., 2020) although these regions shift with atmospheric circulation changes. The overall pattern is robust across different model scenarios and time horizons (Tebaldi and Knutti, 2018), but some deviations from the mean pattern cannot be excluded due to the multiple timescales and non-linear atmospheric or land surface processes involved (Section 8.5.3). Near-term regional changes in precipitation are more uncertain because of a stronger sensitivity to natural variability (Section 8.5.2) and non-GHG anthropogenic forcings (Section 4.4.1.3 and 8.4.3.1).

Projected changes in regional precipitation also arise as a response to changes in large-scale atmospheric circulation (Section 8.2.2.2 and 8.4.2), both in the tropics (Chadwick et al., 2016a; Byrne et al., 2018) and extratropics (Shaw, 2019; Oudar et al., 2020b). Despite variability in simulated changes, CMIP5 climate models consistently project large rainfall changes (of varying sign) over considerable proportions of tropical land during the 21st century (Chadwick et al., 2016a). Since AR5, some robust responses in large-scale

ACCEPTED VERSION SUBJECT TO FINAL EDITING

circulation patterns have been identified. For example, and as further assessed in Section 8.4.2, CMIP6 models project a northward shift in the tropical rain belt over eastern Africa and the Indian Ocean and a southward shift in the eastern Pacific and Atlantic oceans (Mamalakis et al., 2021). A projected strengthening and tightening of the tropical rain belt increases the contrasts between wet and dry tropical weather regimes and seasons. It is less clear how the well understood poleward expansion of the subtropics and mid-latitude storm tracks influences precipitation over sub-tropical and mid-latitude continents (Section 8.2.2.2).

An ensemble of 31 CMIP6 models under the SSP5-8.5 scenario projects increases of precipitation by 10–30% over much of the United States and decreases by 10–40% over Central America and the Caribbean by 2080-2099 (Almazroui et al., 2021). This CMIP6 ensemble also projects an increase in annual precipitation over the southern Arabian Peninsula and a decrease over the northern Arabian Peninsula, as also projected by CMIP3 and CMIP5 models (Almazroui et al., 2020a). Annual mean precipitation is projected to increase over South Asia during the 21st century under all scenarios, although the rate of change varies within the region based on 27 CMIP6 models (Almazroui et al., 2020c). CMIP6 projections also display a reduction in annual mean precipitation over northern and southern Africa while increases are projected over central Africa, under the SSP1-2.6, SSP2-4.5 and SSP5-8.5 scenarios (Almazroui et al., 2020b). The AR6 Atlas assesses that regions where annual mean rainfall is *likely* to increase include the Ethiopian Highlands, East, South and North Asia, southeastern South America, northern Europe, northern and eastern North America, and the Polar Regions. In contrast, regions where annual mean rainfall is *likely* to decrease include southern Africa, coastal West Africa, Amazonia, southwestern Australia, Central America, southwestern South America, and the Mediterranean.

AR5 identified that high-latitude precipitation increase may lead to an increase in snowfall in the coldest regions and a decrease of snowfall in warmer regions due to a decreased number of freezing days. The fraction of precipitation falling as snow and the duration of snow cover was projected to decrease. Heavy snowfall events globally are not expected to decrease significantly with warming as they occur close to the water freezing point, which will migrate poleward and in altitude (O'Gorman, 2014; Turner et al., 2019). There are only a small number of studies evaluating the implications of this mechanism in specific regions. A study for the northeastern US indicates smaller reductions for major snowfall events against the broader decline in snowfall expected from thermodynamic effects (Bintanja and Andry, 2017). Arctic snowfall is projected to decrease as rainfall makes up more of the precipitation (Zarzycki, 2018).

Beyond annual or seasonal mean precipitation amounts, an implication of the parallel intensification of the global water cycle and of the increased residence time of atmospheric water vapour (Section 8.2.1) is that the distribution of daily and sub-daily precipitation intensities will experience significant changes (Pendergrass and Hartmann, 2014b; Pendergrass et al., 2015; Bador et al., 2018; Douville and John, 2020), with fewer but potentially stronger events (*high confidence,* Section 4.3.3). CMIP6 projections show that in the long-term more drier days but more intense single events of precipitation are expected, regardless of scenario (Figure 8.15). Over almost all land regions, it is *very likely* that extreme precipitation will intensify at a rate close to the 7% per 1°C of global warming, but with large spatial differences (Section 11.4; Section 8.2.3.2). The projected increase in precipitable water is expected to lead to an increase in the highest possible precipitation intensities and an increase in the probability of occurrence of extreme precipitation events on the global scale (Neelin et al., 2017), regardless of how annual mean precipitation changes (O'Gorman and Schneider, 2009; O'Gorman, 2015). The projected increase in heavy precipitation intensity is also found for daily mean precipitation intensity though at a lower rate (Pendergrass and Hartmann, 2014a).

An increase in the number of dry days is also projected in several regions of the world (Polade et al., 2014, (Polade et al., 2014; Berthou et al., 2019a)), which can dominate the annual precipitation change at least in the subtropics (Polade et al., 2014; Douville and John, 2020). These findings are supported by CMIP6 projections showing a widespread increase in daily mean precipitation intensity over land (Fig.8.15bdf) as well as an increase in the number of dry days in the subtropics and over Amazonia and Central America (Fig.8.15abc). Such changes in precipitation regimes, as well as the general increase in the frequency and intensity of precipitation extremes (Section 11.4.5), contribute to an overall increase in precipitation variability (Polade et al., 2014; Pendergrass et al., 2017; Douville and John, 2020). This is also found in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

CMIP6 models, which show a stronger increase of interannual variability than in seasonal mean precipitation changes, apart from in the winter extratropics where both quantities increase at the same rate with increasing global warming levels (Fig.8.16).

In summary, it is *virtually certain* that global precipitation will increase with warming due to increases in GHG concentrations and decreases in air pollution. There is *high confidence* that total precipitation will increase in the high latitudes, with a shift from snowfall to rainfall except in the coldest regions and seasons. There is also *high confidence* that precipitation will decrease over the Mediterranean, southern Africa, Amazonia, Central America, southwestern South America, southwestern Australia and coastal West Africa and that monsoon precipitation will increase over South Asia, East Asia and central-eastern Sahel. See Section 8.4.2.4 for a more detailed assessment of changes in regional monsoons. Daily mean precipitation intensities, including extremes, are projected to increase over most regions (*high confidence*). The number of dry days is projected to increase over the subtropics, Amazonia, and Central America (*medium confidence*). There is *high confidence* in an overall increase in precipitation variability over most land areas.

[START FIGURE 8.14 HERE]

Figure 8.14: Projected long-term relative changes in seasonal mean precipitation. Global maps of projected relative changes (%) in seasonal mean of precipitation averaged across 29 CMIP6 models in the SSP2-4.5 scenario. All changes are estimated for 2081-2100 relative to the 1995-2014 base period. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.14 HERE]

[START BOX 8.2 HERE]

BOX 8.2: Changes in water cycle seasonality

Observed changes

AR5 did not highlight observed changes in water cycle seasonality and SRCCL mostly emphasized changes in vegetation seasonality. Since AR5, a number of relevant studies have been published, but often with conflicting results. Based on three *in situ* datasets, reduced precipitation seasonality was identified over 62% of the terrestrial ecosystems analysed from 1950-2009 (Murray-Tortarolo et al. 2017). In contrast, both *in situ* and satellite data show a general increase in the annual range of precipitation from 1979 to 2010, which is dominated by wetter wet seasons (Chou et al., 2013). This paradox may be partly explained by a larger aerosol radiative forcing in the middle of the 20th century as well as by internal variability (Kumar et al., 2015; see also Box 8.1). For instance, the "long rains" over East Africa experienced declining trends in the 1980s and 1990s (Nicholson, 2017), which was linked to anthropogenic aerosols and SST patterns (Rowell et al., 2015), followed by a recent recovery that was linked to internal variability (Wainwright et al., 2019). Two satellite datasets revealed decreased rainfall seasonality in the tropics but an increased seasonality in the subtropics and mid-latitudes since 1979, without clear attribution (Marvel et al., 2017).

Large differences have been found across seven global precipitation datasets, with no region showing a consistent, statistically significant, positive or negative trend over the last three decades (Tan et al., 2020b). Regional studies suggest that observed changes in precipitation seasonality are neither uniform nor stable across the 20th century (Li et al., 2016a; Mallakpour and Villarini, 2017; Sahany et al., 2018; Deng et al., 2019). Since the 1980s, there is however growing evidence that contrasts between wet and dry regimes, including seasonality, have increased (Liu and Allan, 2013; Polson et al., 2013; Murray-Tortarolo et al., 2016; Tapiador et al., 2016; Gallego et al., 2017; Polson and Hegerl, 2017; Barkhordarian et al., 2018; Lan et

ACCEPTED VERSION SUBJECT TO FINAL EDITING

al., 2019; Liang et al., 2020; Schurer et al., 2020).

Additional changes in seasonality may manifest in the timing and duration of wet seasons. A later monsoon onset trend was reported throughout India from 1901 to 2013 (Sahany et al., 2018). Conversely, an earlier rainfall onset was implicated in increased springtime rainfall over the Tibetan Plateau in recent decades (Zhang et al., 2017c). Winter and early spring precipitation over the northwestern Himalaya for the period 1951-2007 shows an increasing trend of daily precipitation extremes in association with enhanced amplitude variations of extra-tropical synoptic-scale systems known as "Western Disturbances" (Cannon et al., 2015; Krishnan et al., 2019; Madhura et al., 2014). In China, an earlier onset was observed during 1961-2012 (Deng et al., 2019). In the African Sahel, rainfall has been most concentrated in the peak of the rainy season since the end of the 20th century (Biasutti, 2019). A shift in the seasonality of Sahelian rainfall, including delayed cessation has also been reported (Nicholson, 2013; Dunning et al., 2018) (Section 10.4.2.1). Over southern Africa, an observed earlier onset (1985-2007) is in contrast to a simulated historical and projected future delay in the wet season (Maidment et al., 2015; Dunning et al., 2018). An increasingly early onset of the North American monsoon has been observed from 1978 to 2009 (Arias et al., 2015). Seasonality changes in the South American monsoon indicate delayed onsets since 1978 (Fu et al., 2013; Yin et al., 2014; Arias et al., 2015; Debortoli et al., 2015; Arvor et al., 2017; Giráldez et al., 2020; Haghtalab et al., 2020; Correa et al., 2021).

In northern high latitudes, a shorter snow season (Zeng et al., 2018a) is mainly due to an earlier onset of spring snowmelt (Peng et al., 2013) which has been attributed to anthropogenic climate change (Najafi et al., 2016). Changes in snow seasonality affect streamflow at the regional scale, with an earlier peak in spring and a possible decrease of low-level flow in summer (Berghuijs et al., 2014; Kang et al., 2016; Dudley et al., 2017), while glacier shrinking can also alter the low-level flow in mountain catchments (Lutz et al., 2014; Milner et al., 2017; Huss and Hock, 2018). This can be partly ameliorated by water management in regulated catchments (Arheimer et al., 2017), but not in large river basins such as the Amazon which also shows an increased seasonality of discharge since 1979 (Liang et al., 2020).

Increasing aridity contrasts between wet and dry seasons over the late 20th century have been suggested (Kumar et al., 2015), with a human-induced decrease of water availability during the dry season over Europe, western North America, northern Asia, southern South America, Australia and eastern Africa (Padrón et al., 2020). Seasonal contrasts in microwave surface soil moisture measurements have also increased over 1979-2016 (Pan et al., 2019). Terrestrial water storage variations derived from gravimetric measurements since 2003 show a strong seasonality which is underestimated by global hydrological models (Scanlon et al., 2019) and whose multidecadal trends are difficult to interpret given the direct effect of enhanced water use (Rodell et al., 2018; Scanlon et al., 2018).

In summary, there is *medium confidence* that the annual range of precipitation has increased since the 1980s, at least in subtropical regions and over the Amazon. There is *low confidence* that this increase is due to human influence and that GHG forcing has already altered the timing or duration of wet seasons. There is *high confidence* that the human-induced retreat of the springtime snow cover and melting of glaciers have already contributed to changes in streamflow seasonality in high-latitude and low-elevation mountain catchments, and *medium confidence* that human activities have also contributed to an increased seasonality of water availability, including a drier dry season, in the extratropics.

Projected changes

AR5 reported with *high confidence* that the contrast between wet and dry seasons will generally increase with global warming and that monsoon onset dates will *likely* become earlier or show little change, while monsoon retreat dates will *likely* be delayed, resulting in a lengthening of the wet season in many regions.

Since AR5, several studies have further documented a projected increase in rainfall seasonality and the understanding of the underlying mechanisms has been improved (Sections 8.2.1 and 8.3.2). CMIP5 models show that the seasonal concentration of annual precipitation will increase over many regions by the end of the 21st century, with robust model agreement in most subtropical regions where an increase in the mean

ACCEPTED VERSION SUBJECT TO FINAL EDITING

number of dry days was also reported in the RCP8.5 scenario (Pascale et al., 2016). The semi-arid, winter rainfall dominated subtropical climate is projected to shift poleward and eastward, with the equatorward margins replaced by a more arid climate type. However, evolving SST patterns and land-ocean warming contrasts cause more complex responses (Alessandri et al., 2015; Polade et al., 2017; Brogli et al., 2019; Zappa et al., 2020). Projections over California show a stronger and shorter wet season (Polade et al., 2017; Dong et al., 2019). Decreases in future winter and spring rainfall are projected over southwestern Australia (Hope et al., 2015). Central Asia is projected to experience wetter winters, associated with an increase in snow depth in the northeastern regions (Li et al., 2019b). Even in a +2°C climate, both extreme precipitation and dryness will increase significantly in the extratropics, amplifying the seasonal precipitation range (Fujita et al., 2018). A single-model study shows that the annual range of precipitation increases globally by 2.6% per °C of global warming in stabilized low-warming scenarios (Chen et al., 2020f).

In the tropics, an amplified annual cycle (by ~3–5%/°C) of global land monsoon hydroclimates (P, $P - E$, and runoff) is projected by CMIP5 models under the RCP8.5 scenario, mostly due to a more intense wet season (Zhang et al., 2019c). A longer rainy season is projected by CMIP6 models over most regional monsoon areas except in the Americas (Moon and Ha, 2020). A delayed onset and cessation of the wet season over West Africa and the Sahel (Dunning et al., 2018) and a slightly delayed onset of South Asian monsoon rainfall (Hasson et al., 2016) are projected by CMIP5 models. CMIP5 projections suggest a strengthening of the annual cycle and a lengthening of the dry season in Southern Amazonia (Fu et al., 2013; Reboita et al., 2014; Boisier et al., 2015; Pascale et al., 2016; Sena and Magnusdottir, 2020). This is further verified by the projections from 6 CMIP6 models (Moon and Ha, 2020). A wet season shorter by 5-10 days by the end to the 21st century is projected for southern Africa (Dunning et al., 2018).

An increase in streamflow seasonality is projected over several large rivers in the low-mitigation RCP8.5 scenario, but with only small changes in the seasonality timing, except in northern high latitudes due to the earlier but potentially slower snowmelt in a warmer world (Eisner et al., 2017; Musselman et al., 2017). At the end of the century in a high-emission scenario, peak snowmelt timing is projected to occur one month earlier and peak water volume is 79% lower in the eastern USA (Rhoades et al., 2018). Earlier snow melt is projected e.g. by 30 days at the end of the 21st century in RCP4.5 for the Sierra Nevada in the western USA (Sun et al., 2018b). Sub-seasonal changes in water availability were found in many regions in the RCP8.5 scenario. However these should be considered with caution given the magnitude of model errors (Ferguson et al., 2018a). Increases in the seasonality of water availability has been found to be more pronounced in areas with high atmospheric evaporative demand, giving rise to a pattern of seasonally variable regimes becoming even more variable (Konapala et al., 2020). RCP4.5 and RCP8.5 projections show a pronounced soil drying in summer and autumn over western Europe, and a springtime drying over northern Europe due to an earlier snowmelt (Ruosteenoja et al., 2018).

A simple relative seasonality metric (Walsh and Lawler, 1981) applied to global projections based on CMIP6 models and SSP scenarios supports previous CMIP5 findings, especially the amplified seasonality of precipitation around the Mediterranean, and across southern Africa, California, southern Australia and the Amazon (Box 8.2, Figure 1). While such changes are not significant in the low-emission SSP1-2.6 scenario, they are consistent with the increased frequency of dry days projected over the same regions (Figure 8.16). In monsoon regions outside the Americas, rainfall seasonality does not show a significant increase even in high-emission scenarios. This challenges previous CMIP5 findings based on the difference between maximum and minimum monthly precipitation in a year (Zhang et al., 2019c) and higher sensitivity to the projected increase in precipitation extremes (Section 11.4.5). In the northern high-latitudes, milder winters are associated with wetter conditions and a decrease in precipitation seasonality.

In summary, the annual range of precipitation, water availability and streamflow will increase with global warming over subtropical regions and the Amazon (*medium confidence*), especially around the Mediterranean and across southern Africa (*high confidence*). The contrast between the wettest and driest month of the year is *likely* to increase by 3 to 5%/°C with global warming in most monsoon regions, in terms of precipitation, water availability (P-E) and runoff (*medium confidence*). There is *medium confidence* that the monsoon season could be delayed in a warmer climate in the Sahel. There is *high confidence* of earlier snowmelt.

[START BOX 8.2, FIGURE 1 HERE]

Box 8.2, Figure 1: Projected long-term changes in precipitation seasonality. Global maps of projected changes in precipitation seasonality (simply defined as the sum of the absolute deviations of mean monthly rainfalls from the overall monthly mean, divided by the mean annual rainfall as in Walsh and Lawler, 1981) averaged across 31 to 33 CMIP6 models in the SSP1-2.6 (b), SSP2-4.5 (c) and SSP5-8.5 (d) scenario respectively. The simulated 1995-2014 climatology is shown in panel (a). All changes are estimated in 2081-2100 relative to 1995-2014. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END BOX 8.2 HERE]

[START FIGURE 8.15 HERE]

Figure 8.15: Projected long-term relative changes in daily precipitation statistics. Global maps of projected seasonal mean relative changes (%) in the number of dry days (i.e. days with less than 1 mm of rain) and daily precipitation intensity (in mm/day, estimated as the mean daily precipitation amount at wet days - i.e., days with intensity above 1 mm/day) averaged across CMIP6 models in the SSP1-2.6 (a,b), SSP2-4.5 (c,d) and SSP5-8.5 (e,f) scenario respectively. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.15 HERE]

[START FIGURE 8.16 HERE]

Figure 8.16: Rate of change in mean and variability across increasing global warming levels. Relative change (%) in seasonal mean total precipitable water (green dashed line), precipitation (red dashed lines), runoff (blue dashed lines), as well as in standard deviation of precipitation (red solid lines) and runoff (blue solid lines) averaged over extra-tropical land in (a) summer and (b) winter, and tropical land in (c) JJA and (d) DJF as a function of global-mean surface temperature for the CMIP6 multi-model mean across the SSP5-8.5 scenario. Extra-tropical winter refers to DJF for Northern Hemisphere and JJA for Southern Hemisphere (and the reverse for extra-tropical summer). Each marker indicates a 21-year period centered on consecutive decades between 2015 and 2085 relative to the 1995–2014 base period. Precipitation and runoff variability are estimated by their standard deviation after removing linear trends from each time series. Error bars show the 5-95% confidence interval for the warmest 5°C global warming level. Figure adapted from (Pendergrass et al., 2017) and updated with CMIP6 models. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.16 HERE]

8.4.1.4 Evapotranspiration

Since AR5, there is a growing body of evidence suggesting that future projections in evapotranspiration are

ACCEPTED VERSION SUBJECT TO FINAL EDITING

driven by changes in temperature and relative humidity (Laîné et al., 2014; Pan et al., 2015; Ukkola et al., 2016a), as well as precipitation patterns, as found in AR5.

Analysis of CMIP5 models suggests that atmospheric evaporative demand will increase over most areas of the world in high-emission scenarios (*virtually certain*), mostly as a consequence of an increase in vapour pressure deficit (Scheff and Frierson, 2014, 2015; Vicente-Serrano et al., 2020b). CMIP5 models also project an increase in evapotranspiration over most land areas (*medium confidence*) (Laîné et al., 2014). However, regional changes in evapotranspiration can also be influenced by changes in soil moisture and vegetation, which modulate the moisture flux from the land to the atmosphere. Several studies of CMIP5 projections suggest that increases in plant water use efficiency will limit or counteract rising evapotranspiration (Milly and Dunne, 2016; Swann et al., 2016; Lemordant et al., 2018; Yang et al., 2018d). However, other studies have found that transpiration increases due to the impact of climate change on growing season length, leaf area, and evaporative demand (Frank et al., 2015; Mankin et al., 2017, 2018, 2019; Guerrieri et al., 2019; Zhou et al., 2019a; Vicente-Serrano et al., 2020b) (Section 8.2.3.3). The parameterizations accounting for these complex physiological processes in global climate models may also be insufficient (Franks et al., 2017; Peters et al., 2018; Peano et al., 2019). Thus, there is currently *low confidence* in the role of vegetation physiology in modulating future projections of evapotranspiration.

CMIP6 models project a geographical pattern of changes in evapotranspiration similar to previous generation models (Figure 8.17), although the magnitude is generally larger than found for CMIP5 projections (Liu et al., 2020b). There is however a strong seasonality in many regions, with a larger relative increase in the winter season of the Northern Hemisphere and smaller relative changes in the summer (Figure 8.17). Evapotranspiration increases in most land regions, except in areas that are projected to become moisture-limited (due to reduced precipitation and increased evaporative demand), such as the Mediterranean, South Africa, and the Amazon basin (*medium confidence*). The patterns of change increase in magnitude from low to high-emission SSP scenarios (*medium confidence*).

In summary, future projections indicate that anthropogenic forcings will drive an increase in global mean evaporation over most oceanic areas (*high confidence*) (Figure 8.17), an increase in global atmospheric demand (*virtually certain*) and an increase in evapotranspiration over most land areas, with the exception of moisture-limited regions (*medium confidence*). However, substantial uncertainties in projections of evapotranspiration, especially at seasonal and regional scales, remain (see also Section 8.2.3.3, Cross-Chapter Box 5.1).

[START FIGURE 8.17 HERE]

Figure 8.17: Projected long-term relative changes in seasonal mean evapotranspiration. Global maps of projected relative changes (%) in seasonal mean of surface evapotranspiration for DJF (left panels) and JJA (right panels) averaged across 29 or 30 CMIP6 models for SSP1.2-6 (a,b), SSP2-4.5 (c,d) and SSP5-8.5 (e,f) scenario respectively. All changes are estimated in 2081-2100 relative to 1995-2014. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.17 HERE]

8.4.1.5 Runoff, streamflow and flooding

AR5 assessed that projected changes in runoff had *low confidence* over the period 2016-2035; however, under the RCP8.5 scenario, runoff increases by 2100 are *likely* in high northern latitudes. This is consistent with projected regional precipitation increases, and that runoff decreases that are *likely* in southern Europe, the Middle East and southern Africa, based on consistency of changes across different generations of models

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and different forcing scenarios. There was considerable uncertainty in the magnitude and direction of change for some regions, largely driven by the uncertainty in projected precipitation changes, particularly across south Asia. For flooding, AR5 assessed with *medium confidence* that flooding would increase over parts of South and Southeast Asia, tropical Africa, northeast Eurasia, and South America, and decrease for parts of northern and Eastern Europe, Anatolia, central Asia, central North America, and southern South America. SR1.5 assessed with *medium confidence* that warming of 2˚C would increase the fraction of global area affected by flood hazard relative to warming of 1.5˚C. Projected climate-driven changes to runoff, streamflow, and flooding will occur in the context of potential human-caused land-use and land-cover changes, which can have a large influence on surface water (Sterling et al., 2013) but which have considerable uncertainty in projections (Prestele et al., 2016).

Since AR5, studies confirm that global mean annual runoff increases with global surface temperature increase (Zhang and Tang, 2014; Zhang et al., 2018e; Lehner et al., 2019), but varies regionally (Chen et al., 2017; Yang et al., 2017; Cook et al., 2020). CMIP5 models display a large spread in the ratio of runoff to precipitation for the present-day climate, which applies also to future runoff changes under global warming (Lehner et al., 2019). In studies of CMIP6 projections, runoff increases in most parts of the northern high latitudes and Asia and north and eastern Africa, and decreases in the Mediterranean region, southern Africa, southern Australia and in parts of western Africa, as well as in Central and South America (Greve et al., 2018; Cook et al., 2020). Projected changes in runoff also vary seasonally. In the Northern Hemisphere, runoff increases during winter since more precipitation falls as rain than snow and decreases in the summer as less snow is available to contribute to runoff during the warm season (Cook et al., 2020). Global maps of projected changes for DJF and JJA are shown in in Figure 8.18, showing projected changes becoming larger and more consistent in the higher emissions scenarios. Runoff projections for CMIP6 are also shown in Figure 8.16 for tropical and extratropical averages at a range of global mean warming levels and in Table 8.1 for global land in different future scenarios. In the tropics, both the mean and interannual variability of runoff increase with warming. The increase in variability is roughly twice as large as the increase in the mean, and has a large spread across models. In the extratropics, changes are small in the summer but there are large increases in the winter, with the mean increasing much more than the variability, in contrast to the tropics.

Changes in streamflow vary regionally and increase in magnitude with emissions scenario, as with runoff (although the two are not equivalent, as runoff includes both surface runoff and streamflow). Streamflow projections additionally require the use of hydrologic models forced by the output from climate models and have not been as widely explored as they are not variables directly included in climate models. On an annual basis, streamflows have been projected to increase in the Northern high latitudes and tropical Asia and Africa, and to decrease in the Mediterranean, tropical South America, and South Africa (Döll et al., 2018b). For a 4°C global warming, half of the global land area is projected to be exposed to increased high flows (average increase 25%), while about 60% may be exposed to decreased low flows (average decrease 50%) (Asadieh and Krakauer, 2017).

Changes in the seasonality of runoff and streamflow are assessed in Box 8.2. The seasonality of runoff and streamflow (calculated as the annual difference between the wettest and driest months of the year), is expected to increase with global warming in the subtropics, especially in the Mediterranean and southern Africa with *high confidence*, and in the Amazon with *medium confidence*. For regions where snowmelt is an important contributor to streamflow, there is *high confidence* that snowmelt occurring earlier in the year will result in peak flows also occurring earlier in the year, and *medium confidence* that reduced snow volume and the weaker solar radiation earlier in the year will reduce the most intense flows. In roughly half of 56 large-scale glacierized drainage basins, projected runoff changes show an increase until a maximum is reached, beyond which runoff steadily declines because of limited ice volumes (Huss and Hock, 2018).

As future changes in flood events are assessed in Chapters 9 and 11, only a summary is presented here. There are a number of complicating factors for projecting both pluvial (overland) and fluvial (river) flooding that limit confidence in their assessment. In addition to precipitation, flooding also depends on basin and river characteristics such as permeability, antecedent soil moisture, and antecedent flow levels for river flooding, so projections of extreme precipitation and flooding are not always closely linked (Section 8.2.3.2).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Possible changes in water resources management and land use add another layer of complexity to future changes. There is *medium confidence* in a general increase in pluvial and fluvial flooding, although there are large geographical variations in magnitude. There are increases in flooding in the West Amazon, the Andes, and northern Eurasia (Chapter 11, Section 11.5.5). There is *medium confidence* in future increases in urban and coastal floods (Chapter 11, Section 11.5.5), and *high confidence* that some coastal regions will experience large increases in surge flooding (Chapter 9, Section 9.6.4.2). There is *medium confidence* in an increase in compound flood events (Chapter 11, Section 11.8.1). Although there is currently insufficient evidence for a confident projection, flooding due to rain-on-snow events can be expected to decrease where snow decreases (Chapter 11, Section 11.8.3), and the seasonality of snowmelt-related flooding can be expected to shift in regions with temperature-driven shifts in the snowmelt season (e.g., Vormoor et al., 2015). Glacier lake outburst floods (GLOFs) are expected to increase substantially, in delayed response to glacier recession but with *low confidence*, due to the small number of studies and the complexity of the processes involved (Chapter 9, Section 9.5.3.3).

In summary, there is *medium confidence* that global runoff will increase with global warming, but with large regional and seasonal variations. There is *high confidence* that runoff will increase in the northern high latitudes and decrease in the Mediterranean region and southern Africa. There is *medium confidence* that runoff will increase in regions of central and eastern Africa, and decrease in Central America and parts of southern South America, with the magnitude of the change increasing with emissions. There is *medium confidence* that the seasonality of runoff and streamflow will increase with global warming in the subtropics. In snow-dominated regions, there is *high confidence* that peak flows associated with spring snowmelt will occur earlier in the year and *medium confidence* that snowmelt-induced runoff will decrease with reduced snow, except in glacier-fed basins where runoff may increase in the near term. There is *medium confidence* that flooding in general will increase, although with considerable variation based on geographic region and flood type. These projected climate-related changes will occur in the context of human-caused land-use and land-cover changes, which may also have a large influence.

[START FIGURE 8.18 HERE]

Figure 8.18: Projected long-term relative changes in seasonal mean runoff. Global maps of projected relative change (%) in runoff seasonal mean for DJF (left panels) and JJA (right panels) averaged across CMIP6 models SSP1.2-6 (a,b), SSP2-4.5 (c,d) and SSP5-8.5 (e,f) scenario respectively. All changes are estimated in 2081-2100 relative to 1995-2014. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.18 HERE]

8.4.1.6 Aridity and drought

AR5 concluded that regional to global-scale projections of aridity and drought remained relatively uncertain compared to other aspects of the water cycle. It reported that there is a *likely* increase in drought occurrence (*medium confidence*) by 2100 in regions that are currently drought-prone under the RCP8.5 scenario due to projected decreases in soil moisture. It stated that it is *likely* that the most prominent projected decreases in soil moisture would occur in the Mediterranean, southwest USA, and southern Africa, consistent with projected changes in the Hadley Circulation and increased surface temperatures. These AR5 conclusions are generally supported by more recent analyses of CMIP5 models (Feng and Fu, 2013; Berg et al., 2017; Cook et al., 2018).

Results from the latest generation of models in CMIP6 are largely congruent with CMIP5. Consistent with the coherent nature of warming in future projections, increases in vapour pressure deficit and evaporative demand are widespread and consistent across regions, seasons, and models, increasing in magnitude in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

accordance with the emissions scenario (Figure 8.19) (*high confidence*) (Scheff and Frierson, 2014, 2015; Vicente-Serrano et al., 2020b). Even under a low-emissions scenario (SSP1-2.6), projections of soil moisture show significant decreases in the Mediterranean, southern Africa, and the Amazon basin (*high confidence*) (Figure 8.19). Under mid- and high-emissions scenarios (SSP2-4.5 and SSP5-8.5), coherent declines emerge across Europe, westernmost North Africa, southwestern Australia, Central America, southwestern North America, and southwestern South America (*high confidence*) (Figure 8.19) (Cook et al., 2020). Compared to CMIP5 results, CMIP6 models exhibit more consistent drying in the Amazon basin (Parsons, 2020), more extensive declines in total soil moisture in Siberia (Cook et al., 2020), and stronger declines in westernmost North Africa and southwestern Australia (Figure 8.19).

Soil moisture in the top soil layer (10 cm) shows more widespread drying than total soil moisture, reflecting a greater sensitivity of the upper soil layer to increasing evaporative demand (Berg et al., 2017) (Figure 8.19). Conversely, total column soil moisture represents the carry-over of moisture from previous seasons deeper in the soil column, and potentially higher sensitivity to vegetation processes (Berg et al., 2017; Kumar et al., 2019). Central America, the Amazon basin, the Mediterranean region, southern Africa, and southwestern Australia are projected to experience significant declines in total soil moisture, whereas declines in Europe (north of the Mediterranean), western Siberia, and northeastern North America are limited to the surface (Figure 8.19). It should be noted that because models differ in their number of hydrologically active layers, there is less confidence in total soil moisture projections than surface soil moisture projections. Based on surface soil moisture projections, more than 40% of global land areas (excluding Antarctica and Greenland) are expected to experience robust year-round drying, even under lower emissions scenarios (Cook et al., 2020). The percentage of land area experiencing drying is slightly lower when runoff is used as an aridity metric instead (20–30%); taking this into consideration, it is estimated that about a third of global land areas will experience at least moderate drying in response to anthropogenic emissions, even under SSP1-2.6 (*medium confidence*) (Cook et al., 2020).

Although there are regions where multiple models predict consistent and significant changes in soil moisture, as with evapotranspiration (Section 8.4.1.4), there is still uncertainty in these projections related to the response of plants to elevated CO_2. Most models project increases in two variables that have opposite effects on surface water availability: plant water use efficiency (WUE) and leaf area index (LAI) (see Section 8.4.1.4). As discussed in Section 8.2.3.3, 8.3.1.4, and 8.4.1.4, there is *low confidence* in how these changes in plant physiology will affect future projections of evapotranspiration, and likewise, drought and aridity.

[START FIGURE 8.19 HERE]

Figure 8.19: Projected long-term relative changes in annual mean soil moisture and vapour pressure deficit. Global maps of projected relative changes (%) in annual mean vapour pressure deficit (left), surface soil moisture (top 10cm, middle) and total column soil moisture (right) from available CMIP6 models for the SSP1.2-6 (a,b,c), SSP2-4.5 (d,e,f) and SSP5-8.5 (g,h,i) scenarios respectively. All changes are estimated for 2081-2100 relative to a 1995-2014 base period. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement ("Robust change"), where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.19 HERE]

Changes in meteorological (precipitation-based) drought duration and intensity in CMIP6 models are more robust than projected changes in mean precipitation, more than found in CMIP5 projections (Ukkola et al., 2020). Significant increases in drought duration are expected in Central America, the Amazon basin, southwestern South America, the Mediterranean, westernmost North Africa, southern Africa, and southwestern Australia, on the order of 0.5–1 month for a moderate emissions scenario (SSP2-4.5) and 2 months for a high emissions scenario (SSP5-8.5) (Ukkola et al., 2020). Drought intensity is projected to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

increase in the tropics, mainly in the Amazon basin, central Africa, and southern Asia, as well as in Central America and southwestern South America (Ukkola et al., 2020). The CORDEX South Asia multi-model ensemble projections indicate an increase in the frequency and severity of droughts over central and northern India during the 21st century, under the RCP4.5 and RCP8.5 scenarios *(medium confidence)* (Mujumdar et al., 2020). Under middle or high emissions scenarios, the likelihood of extreme droughts (events that have magnitudes equal to or less than the 10th percentile of the 1851–1880 baseline period) increases by 200–300% in the Amazon basin, southwestern North America, Central America, the Mediterranean, southern Africa, and southwestern South America (Cook et al., 2020). Even under a low emissions scenario (SSP1-2.6), the likelihood of extreme droughts increases by 100% in southwestern North America, southwestern South America, the Amazon, the Mediterranean, and southern Africa (Cook et al., 2020). Thus, there is *high confidence* that drought severity and intensity will increase in the Mediterranean, southern Africa, southwestern South America, southwestern North America, southwestern Australia, Central America and the Amazon basin.

Paleoclimate records provide context for these future expected changes in drought and aridity. In the Mediterranean, western North America, and central Chile, there is *high confidence* that climate change will shift soil moisture (as represented by the Palmer Drought Severity Index) outside the range of observed and reconstructed values spanning the last millennium (Cook et al., 2014; Otto-Bliesner et al., 2016) (Figure 8.20). Warmer temperatures, leading to increased evaporative losses, are clearly implicated in the projected future drying in these semi-arid regions (Dai et al., 2018), emphasizing the central role that warming plays in driving increased evaporative demand (Vicente-Serrano et al., 2020b). In contrast, future trajectories are more uncertain in regions like central Asia and eastern Australia–New Zealand where projected changes in precipitation and soil moisture are less coherent (Hessl et al., 2018) (Figure 8.19, 8.20). More information on projected changes in drought, including specific categories or drought, can be found in Section 11.6.5 and Section 12.4.

In summary, there is *high confidence* that soil moisture will decline in semi-arid, winter-rainfall dominated areas including the Mediterranean, southern Africa, southwestern North America, southwestern South America, and southwestern Australia, as well as in Central America and the Amazon basin. In general, these regions are expected to become drier both due to reduced precipitation (*medium confidence*) and increases in evaporative demand (*high confidence*). These same regions are *likely* to experience increases in drought duration and/or severity (*high confidence*). The magnitude of expected change scales with emissions scenarios (*high confidence*) but even under low-emissions trajectories, large changes in drought and aridity are expected to occur (*high confidence*) with consequences for regional water availability. In the Mediterranean, central Chile, and western North America, future aridification will far exceed the magnitude of change seen over the last millennium (*high confidence*).

[START FIGURE 8.20 HERE]

Figure 8.20: Past-to-future drought variability in paleoclimate reconstructions and models for select regions. On the left (a,c,e,g,i), tree-ring reconstructed Palmer Drought Severity Index (PDSI) series (black line) for the Mediterranean (10˚W–45˚E, 30˚–47˚N; Cook et al., 2015, 2016), central Chile (70˚–74˚W, 32˚–37˚S; Morales et al., 2020), western North America (117˚–124˚W, 32˚–38˚N; Cook et al., 2010; Griffin and Anchukaitis, 2014), Eastern Australia and New Zealand (136˚–178˚E, 46˚–11˚S; Palmer et al., 2015), and Central Asia (99˚–107˚E, 47˚–49˚N; Pederson et al., 2014; Hessl et al., 2018) plotted in comparison to the past-to-future fully-forced simulations from four ensemble members (thin blue lines) from the NCAR CESM Last Millennium Ensemble (thick blue line = ensemble mean) (Otto-Bliesner et al., 2016) for the same regions. The shaded area represents the range (10th to 90th percentile) of historical and future (RCP8.5) PDSI (Penman-Monteith) simulations from 15 CMIP5 models and 34 ensemble members for the same regions (1900–2100; Cook et al., 2014). On the right (b,d,f,h,i), the distribution of annual PDSI values from the past and present (850 to 2005 CE) (black) is compared to the future distribution (2006 to 2100 CE) (blue). The distributions show each of the four ensemble members from the CESM LME simulations. The future component of the CESM LME follows the RCP8.5 scenario. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[END FIGURE 8.20 HERE]

8.4.1.7 Freshwater reservoirs

8.4.1.7.1 Glaciers

Previous assessments have concluded that recent warming has led to a reduction in low-elevation snow cover (SROCC, *high confidence*), permafrost (SROCC, *high confidence*), and glacier mass (AR5, *high confidence*; SROCC, *very high confidence*). SROCC noted that these declines are projected to continue almost everywhere over the 21st century (*high confidence*), with complete glacier loss expected in regions with only small glaciers (*very high confidence*). SROCC supported the AR5 finding that glacier recession would continue even without further changes in climate. SROCC concluded that cryosphere changes had already altered the seasonal timing and volume of runoff (*very high confidence*), which in turn had affected water resources and agriculture (*medium confidence*), and projected peak water runoff had already been reached before 2019 in some of the glacier regions considered.

Chapter 9 provides detailed assessment of glacier observations and projections (Figure 9.20 and 9.21, see Section 9.5.1). Here, a summary of their key findings is presented. Since SROCC, the coordinated glacier model intercomparison project (GlacierMIP (Marzeion et al., 2020), see also Box 9.3) has advanced modelling efforts. Global glacier volumes will substantially decline in coming decades regardless of emissions scenario; under a high emission scenario some areas will lose nearly all of their glacier mass (Section 9.5.1.3). The projected global glacier mass loss over 2015-2100 is 29 000 ± 20 000 Gt for SSP1-2.6 to 58 000 ± 30 000 Gt for SSP5-8.5 (Section 9.5.1). Because of their lagged response to warming, glaciers will continue to lose mass for decades even if global temperature is stabilized (*very high confidence*) (Section 9.5.1).

Global glacier mass loss projections show a scenario-dependent geographic partitioning of when peak in runoff occurs (Marzeion et al., 2020), consistent with previous studies (Radić et al., 2014; Huss and Hock, 2018; Hock et al., 2019a). Under a low emission scenario (Marzeion et al., 2020) all regions exhibit runoff in the decades prior to 2050. Under a high emission scenario however, low and mid-latitude regions show peak runoff before approximately 2060, whereas Arctic regions peak in later decades around 2070-2090. Antarctic glacier losses will not have peaked by the end of the century in the high emission scenario. Globally, peak runoff of 2.5 to 3 mm / year sea level equivalent occurs around 2090 (Marzeion et al., 2020). Regional projections are presented in detail in Section 9.5.1 and Figure 9.21, and briefly summarized below.

Himalaya and Central Asia: Glaciers in the Himalayas feed ten of the world's most important river systems and are critical water sources for nearly two billion people (Wester et al., 2019) However they are some of the most vulnerable 'water towers' (Immerzeel et al., 2020) that are projected to experience volume losses of approximately 30 to 100% by 2100 depending on global emissions scenarios (Marzeion et al., 2020). Under mid-range emissions scenarios glaciers in this region are projected to reach peak runoff during the period 2020 to 2040 (Marzeion et al., 2020).

Alaska, Yukon, British Columbia: Post-AR5 but pre-SROCC projections indicated a potential 70 ± 10% reduced volume of glacier ice in western Canada relative to 2005 (Clark et al., 2015), with few glaciers remaining in the Interior and Rockies regions and maritime glaciers in northwestern British Columbia surviving only in a diminished state. Recent global projections support these earlier findings, showing that glacier mass in Western Canada and the United States may reduce by 50% under low emissions scenarios and be completely lost under the highest emissions and most sensitive glacier model combinations (Marzeion et al., 2020) (Figure 9.21). Arctic Canada and Alaskan glaciers are projected to experience more modest mass loss (0 to 60% depending on region, scenario, and model; Marzeion et al., 2020).

Andes: Huss and Hock (2018) concluded that peak glacier mass was reached prior to 2019 for 82–95% of the glacier area in the tropical Andes. This is consistent with more recent global model simulations that show mass loss rates from low latitude glaciers that universally decline from the start of simulations in 2015, regardless of emissions scenario (Marzeion et al., 2020). Peak runoff in low-latitude Andean glacier-fed

ACCEPTED VERSION SUBJECT TO FINAL EDITING

rivers has therefore already passed (Frans et al., 2015; Polk et al., 2017) but in the Southern Andes may occur in the latter half of the century under high emission scenarios (Marzeion et al., 2020).

In summary, glaciers are projected to continue to lose mass under all emissions scenarios *(very high confidence*). Runoff from glaciers is projected to peak at different times in different places, with maximum rates of glacier mass loss in low latitude regions taking place in the next few decades in all scenarios (*high confidence*). While runoff from small glaciers will typically decrease because of glacier mass depletion, runoff from larger glaciers will increase with increasing global warming until glacier mass is similarly depleted, after which runoff peaks and then declines and which tends to occurs later in basins with larger glaciers and higher ice-cover fractions (*high confidence*). Glaciers in the Arctic and Antarctic will continue to lose mass through the latter half of the century and beyond (*high confidence*).

8.4.1.7.2 Seasonal snow cover

AR5 assessed as *very likely* that the amount and seasonal duration of Northern Hemisphere snow cover will reduce under global warming (AR5 Section 11.3.4.2, Section 12.4.6.2). Changes in the total amount of water in the snow cover (snow water equivalent) are less certain because of the competing influences of temperature and precipitation.

As snow cover is assessed in Chapter 9 (Section 9.5.3.3), only an overview of that assessment is provided here. Changes in seasonality of snow cover are assessed in Box 8.2. The continued consistency of reported results across all generations of model projections, along with improvements in process understanding, has increased confidence in snow cover projections since AR5.

In summary, based on the results of Chapter 9, it is now *virtually certain* that future Northern Hemisphere snow cover extent and duration will continue to decrease with global warming. While most studies have focused on the Northern Hemisphere, process understanding suggests with *high confidence* that these results apply to the Southern Hemisphere as well. There is *high confidence* in snowmelt occurring earlier in the year. Changes to the timing and amount of snowmelt will have a strong influence on all the other aspects of the water cycle in regions with seasonal snow, including run-off, soil moisture, and evapotranspiration.

8.4.1.7.3 Wetlands and lakes

AR5 did not include specific projections for wetlands and lakes. SRCCL and SROCC provided some discussion of wetlands projections. For coastal wetlands, SRCCL noted the importance of sea level rise for increased saltwater intrusion, although projections of coastal wetland area with sea level rise are inconclusive. Some studies project substantial decreases (Spencer et al., 2016) while others indicate possible increases (Schuerch et al., 2018). SRCCL also noted the general expectation for decreases in water resources, including wetlands, in areas of decreased rainfall due to increased evaporation.

Local studies of inland wetlands project decreases in a range of environments including mountain (Lee et al., 2015), mid-to-high latitude (Zhao et al., 2018b), and prairie (Sofaer et al., 2016) regions. In addition to affecting wetland extent and density, changes in flooding can also affect the connectivity between wetlands and rivers (Karim et al., 2016). Despite a number of uncertainties underlying the general response of wetlands to climate change, there are multiple ways climate change may cause considerable stress on both inland and coastal wetlands (Junk et al., 2013; Moomaw et al., 2018).

Widespread changes are also projected for lakes (Woolway et al., 2020), including changes in lake temperature (Fang and Stefan, 1999; Sahoo et al., 2016), ice (Sharma et al., 2019), evaporation (Wang et al., 2018d), and stability and mixing (Woolway and Merchant, 2019). Note that lake ice is also considered in Chapter 12 of this Report. To date, carbon dioxide-induced lake acidification, analogous to ocean acidification, has not been the focus of many studies but may occur with continued emissions (Phillips et al., 2015). While glacier lakes in general increase with melting glaciers (Linsbauer et al., 2016; Colonia et al., 2017; Magnin et al., 2020) no clear projections are currently available (see discussion in Chapter 9). Projections of lake level means and variability show substantial changes for individual lakes (Bucak et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2017; Li et al., 2021) but can be sensitive to methodology, due to the competing processes involved (Notaro et al., 2015). Projected changes to wetlands and lakes due to climate change will occur in the context of widespread and continuing human-caused conversion and degradation of wetlands (e.g, Davidson, 2014), and where water withdrawals have a large impact on lake levels (e.g., (Micklin, 2016)).

In summary, there is *medium confidence* that inland wetland extent will decrease in regions of projected precipitation decrease and evaporation increase, and *high confidence* that sea level rise will increase saltwater intrusion into coastal wetlands. However, there is *low agreement* on the influence of sea level rise on the extent of coastal wetlands. Regarding lakes, there is *high confidence* for temperature increases and ice decreases, based on both projections and physical expectations, and *low confidence* for non-homogeneous decreases in mixing, given there is currently *limited evidence*.

8.4.1.7.4 Groundwater

Groundwater projections were not assessed in AR5. Groundwater processes are not explicitly included in most current CMIP6 models and so must be calculated separately with hydrologic models (e.g., Taylor et al., 2013; Cuthbert et al., 2019a). A range of factors are important in assessing groundwater projections, including the mean difference between precipitation and evaporation, the intensity of precipitation (Taylor et al., 2013b), and in changes in snow (Tague and Grant, 2009), glaciers (Gremaud et al., 2009), and permafrost (Okkonen and Kløve, 2011). Climate impacts on groundwater are occurring in the context of severe and growing human-caused groundwater depletion (Konikow and Kendy, 2005), Rodell et al. 2018; (Bierkens and Wada, 2019), also see WGII), and water scarcity issues (Mekonnen and Hoekstra, 2016). Climate-related changes to the water cycle can influence water demand (for example, precipitation decreases in an irrigated area), and anthropogenic groundwater depletion can influence the water cycle through interactions with surface energy fluxes, surface water, and vegetation (Cuthbert et al., 2019a), although uncertainties in estimates of future groundwater depletion are large ((Smerdon, 2017), (Bierkens and Wada, 2019)). Some aspects of groundwater change will be irreversible, including the increase of saltwater intrusion into coastal aquifers with sea level rise (Werner and Simmons, 2009), and depletion of fossil aquifers and aquifers with very long recharge times ((Bierkens and Wada, 2019)).

Globally, two modelling studies have shown substantial decreases in groundwater in regions including the Mediterranean, northeastern Brazil and southwestern Africa, with less clarity for other regions (Döll, 2009), Portmann et al., 2013). Recent regional-scale analyses of the impact of water cycle changes on groundwater recharge (e.g. Meixner et al., 2016; Shrestha et al., 2018; Tillman et al., 2017) suggest changes in both seasonality and spatial distribution, which are amplified under a higher greenhouse-gas emission scenario (i.e., RCP 8.5 compared to RCP4.5). Seasonality changes are linked to increases during wet winter periods and declines during dry summer periods. Changes in spatial distribution are linked with increases in more humid regions and declines in more arid locations. Uncertainty in projections of groundwater were found to be substantially influenced by the conceptual and numerical models employed to estimate groundwater recharge (Meixner et al., 2016; Hartmann et al., 2017). Accordingly, current research on estimating water cycles change on groundwater includes a focus on improving the numerical representation of groundwater systems (Bierkens et al., 2015; Döll et al., 2016)).

In summary, based on known limitations in current modelling, no confident assessment of groundwater projections is made here, although important climate-related changes in groundwater recharge are expected. In many environments, such climate-related impacts are expected to occur in the context of substantial human groundwater withdrawals depleting groundwater storage.

8.4.2 Projected changes in large scale phenomena and regional variability

A weakening of the tropical circulation represents a balance between thermodynamic increases in low level water vapour (~7%/K) and smaller increases in global precipitation (1-3%/K) that are influenced by rapid adjustments to radiative forcings as well as slow responses to warming (Bony et al., 2013; Chadwick et al., 2013; Ma et al., 2018, Section 8.2.2.2). Since AR5, additional drivers of tropical circulation weakening have

ACCEPTED VERSION SUBJECT TO FINAL EDITING

been identified, including mean SST warming and changes in spatial patterns of SST (He and Soden, 2015), and the direct CO_2 radiative effect (Bony et al., 2013; Merlis, 2015 ; He and Soden, 2015).

8.4.2.1 ITCZ and tropical rain belts

CMIP5 projections show no consistent shift in the zonal mean position of the ITCZ (Byrne et al., 2018; Donohoe et al., 2013; Donohoe and Voigt, 2017). The ITCZ position is strongly connected to cross-equatorial energy transport (Bischoff and Schneider, 2014; Kang et al., 2008), which also shows no consistent change in future projections (Donohoe et al., 2013). Since AR5 it has been reported that most CMIP5 models project a narrowing of the ITCZ in response to surface warming together with intensified ascent in the core region and weakened ascent on the ITCZ edges (Lau and Kim, 2015; Byrne et al., 2018), implying a narrowing of precipitation regions influenced by the ITCZ. Modelled changes in the width and intensity of the zonal mean ITCZ are strongly anti-correlated, i.e. narrowing is associated with increased intensity while broadening with decreased intensity. Such changes are associated with changes in tropical high cloud fraction and outgoing longwave radiation (Su et al., 2017; Byrne et al., 2018).

Regional shifts in tropical convergence zones are much larger than their zonal mean, and associated regional changes in precipitation (Chadwick et al., 2013; Mamalakis et al., 2021) are characterized by considerable uncertainties across models (Kent et al, 2015; Oueslati et al., 2016). Over the tropical oceans, shifts in rain bands are strongly coupled with changes in SSTs (Xie et al., 2010; Huang et al., 2013). Over tropical land, factors including remote SST increases (Giannini, 2010), the direct CO_2 effect (Biasutti, 2013) and land-atmosphere interactions (Chadwick et al., 2017; Kooperman et al., 2018) influence projections. CMIP6 models project a clear northward ITCZ shift over eastern Africa and the Indian Ocean and a southward shift over the eastern Pacific and Atlantic oceans, as a result of regionally-contrasting inter-hemispheric energy flows (Mamalakis et al., 2021). The northward movement of the ITCZ over Africa has been linked to an intensification of the Saharan heat low associated with greenhouse gas warming (Dong and Sutton, 2015), causing the tropical rain belt to seasonally migrate farther northward and reside there longer (Cook and Vizy, 2012; Dunning et al., 2018). In southern Africa, the projected delay in the wet season onset (Dunning et al., 2018) is also associated with a circulation-based northward shift in the tropical rain band (Lazenby et al., 2018).

In summary, consistent with the AR5, the overall weakening of the tropical circulation is projected in CMIP5 and CMIP6 simulations with *high confidence*. It is *likely* that the zonal mean of the ITCZ will narrow and strengthen in the core region with projected surface warming (*high confidence*). Distinct regional shifts in the ITCZ will be associated with regional changes in precipitation amount and seasonality (*medium confidence*).

8.4.2.2 Hadley Circulation and subtropical belt

AR5 found that the Hadley cells are *likely* to slow down and expand in response to radiative forcing, but with considerable internal variability. Given the complexities in forcing mechanisms, AR5 assigned *low confidence* to near-term changes in the structure of the Hadley circulation. The widening Hadley cells were expected to result in a poleward expansion of subtropical dry zones.

Model simulations since AR5 project a more noticeable and consistent weakening of the Northern Hemisphere winter Hadley cell than the Southern Hemisphere winter cell (Seo et al., 2014; Zhou et al., 2016), related to changes in meridional temperature gradient, static stability, and tropopause height (Seo et al., 2014; D'Agostino et al., 2017). Changes in SST patterns reduces the magnitude of Hadley cell weakening (Gastineau et al., 2009; Ma et al., 2012). There is considerable structure in Hadley circulation strength changes with longitude, associated with cloud-circulation interactions (Su et al., 2014). Subtropical anticyclones are projected to intensify over the north Atlantic and south Pacific but to weaken elsewhere (He et al., 2017).

A consistent poleward expansion of the edges of the Hadley cells is projected (Nguyen et al., 2015; Grise

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and Davis, 2020), particularly in the Southern Hemisphere, consistent with observed trends (Nguyen et al., 2015) (Fig 8.21, 8.3.2.2). The main driver of future expansion appears to be greenhouse gas forcing (Grise et al., 2019), with uncertainty in magnitude due to internal variability (Kang et al., 2013). Proposed mechanisms for poleward expansion include increased dry static stability (Lu et al., 2007 ; Frierson et al., 2007), increased tropopause height (Chen and Held, 2007; Chen et al., 2008), stratospheric influences (Kidston et al., 2015) and radiative effects of clouds and water vapour (Shaw and Voigt, 2016, see also 4.5.1.5). Hadley cell expansion is thought to be associated with the precipitation declines projected in many subtropical regions (Shaw and Voigt, 2016), but more recent work suggests that these reductions are mainly due to the direct radiative effect of CO_2 forcing (He and Soden, 2015), land-sea contrasts in the response to forcing (Shaw and Voigt, 2016; Brogli et al., 2019) and SST changes (Sniderman et al., 2019). In semi-arid, winter rainfall-dominated regions (such as the Mediterranean), thermodynamic processes associated with the land-sea thermal contrast and lapse rate changes dominate the projected precipitation decline in summer, whereas circulation changes are of greater importance in winter (Brogli et al., 2019). The hydroclimates in these regions are projected to evolve with time due to changing contributions from rapid atmospheric circulation changes and their associated SST responses, as well as slower SST responses to anthropogenic forcing (Zappa et al., 2020).

In summary, CMIP5 and CMIP6 models project a weakening of the Hadley cells, with *high confidence* for the Northern Hemisphere in boreal winter and *low confidence* for the Southern Hemisphere in austral winter. The Hadley cells are projected to expand polewards with global warming, most notably in the Southern Hemisphere (*high confidence*). There is currently *low confidence* in the impacts on regional precipitation in subtropical regions.

8.4.2.3 Walker circulation

AR5 determined that the Pacific Walker circulation was *likely* to slow down over the 21st century, which would lead to decreased precipitation over the western tropical Pacific and increases over the central and eastern Pacific. Recent studies show consistency with AR5 conclusions but also show an eastward shift over the Pacific, mostly due to a shift towards more "El Niño–like" conditions under global warming (Bayr et al., 2014). Other studies suggest that the weakening of the Walker circulation is related to the response of the western North Pacific monsoon and to changing land–sea temperature contrasts, while a positive ocean–atmosphere feedback amplifies the weakening of both east–west SST gradient and trade winds in the tropical Pacific (Zhang & Li, 2017).

Since AR5, the paradox between the projected weakening and the observed strengthening of the Walker circulation since the 1990s (Section 8.3.2.2) has triggered debate about the drivers of these changes (England et al., 2014; McGregor et al., 2014; Kociuba and Power, 2015; Vilasa et al., 2017; Chung et al., 2019). Projected changes in equatorial SST gradients are not entirely consistent with observed trends (Coats and Karnauskas, 2017; Seager et al., 2019a), and one CMIP5 model that projects a future strengthening of the Walker circulation is more consistent with observations than other models (Kohyama et al., 2017). Other studies suggest that these differences arises from the dominant influence of internal climate variability to the observed trends (Chung et al., 2019), or as a consequence of a systematic cold bias of most CMIP5 models in their Equatorial Pacific cold tongues (Seager et al., 2019a). However, the latter hypothesis is based on a simplified model of tropical Pacific dynamics and is not consistent with the current physical understanding of the tropical circulation response to increasing CO_2 levels (Section 8.2.2.2) or with independent paleoclimate evidence suggesting a weaker Walker circulation under warmer climates (Tierney et al., 2019; McClymont et al., 2020). Different time scales of the tropical Pacific responses to global warming have been highlighted by numerical experiments with both comprehensive and simplified models. Results suggest a transient strengthening of the Walker circulation related to Indian Ocean warming (Zhang et al., 2018b), followed by a slower weakening linked to a strengthened eastern Pacific cold tongue warming emerging after 50-100 years (Heede et al., 2020, Section 7.4.4.2.1).

CMIP6 projections provide further evidence of a significant long-term weakening of the Walker circulation (Fig. 8.21). For instance, a pronounced weakening of the upper-level tropical easterly jet is projected both

ACCEPTED VERSION SUBJECT TO FINAL EDITING

over the Indian Ocean and tropical eastern Pacific, where declines are projected to exceed 70% by 2100 in the high-emission SSP5-8.5 scenario (Huang et al., 2020a). CMIP6 models agree on a future decrease of the equatorial zonal temperature gradient (Fredriksen et al., 2020), which can lead to weaker trade winds over the tropical Pacific. However, CMIP6 models show a diversity of SST warming patterns in the tropical Pacific (Freund et al., 2020), which contributes to uncertainties in the response of both Walker circulation and ENSO to continued warming.

In summary, there is *high confidence* that the Pacific Walker circulation will weaken by the end of the 21st century, and will be associated with decreased precipitation over the western tropical Pacific and increases farther east. Discrepancies between observed and simulated changes in SSTs in the tropics indicate that a temporary strengthening of the Walker Circulation can arise from a transient response to GHG radiative forcing (*low confidence*) and from internal variability (*medium confidence*).

[START FIGURE 8.21 HERE]

Figure 8.21: Schematic depicting large-scale circulation changes and impacts on the regional water cycle. The central figures show precipitation minus evaporation (P-E) changes at 3°C or global warming relative to a 1850-1900 base period (mean of 23 CMIP6 SSP5-8.5 simulations). Annual mean changes (large map) include contours depicting control climate P-E=0 lines with the solid contour enclosing the tropical rain belt region and dashed lines representing the edges of subtropical regions. Confidence levels assess understanding of how large-scale circulation change affect the regional water.

[END FIGURE 8.21 HERE]

8.4.2.4 Monsoons

In AR5, monsoon precipitation over land was projected to intensify by the end of the 21st century, due to thermodynamic increases in moisture convergence despite weakening of the tropical circulation (see Section 8.2.1.3). Following the definition of regional monsoons in Annex V and Figure 8.11, and the assessment of the observed changes (Section 8.3.2.4), here we provide an assessment of projected changes in regional monsoons. Assessment is provided either in terms of SSP and RCP scenarios and global warming levels available since AR5, or from the newly available CMIP6 projections (Figure 8.22 and Table 8.2). Table 8.2 provides projected changes across the five SSPs used in this report for precipitation (mm/day), P-E (mm/day) and runoff (mm/day) over the regional monsoons for the mid (2041-2060) and long term (2081-2100).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Table 8.2: Monsoon mean water cycle projections in the medium term (2041-2060) and long term (2081-2100) relative to present day (1995-2014), showing present day mean and 90% confidence range across CMIP6 models (historical experiment) and projected mean changes and the 90% confidence range across the same set of models and a range of shared socioeconomic scenarios. All statistics are in units of mm/day. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

Figure 8.22: Projected regional monsoons precipitation changes. Percentage change in projected seasonal mean precipitation over regional monsoon domains (as defined in Fig 8.11, Section 8.3.2.4 and Annex V) for near-term (2021-2040), mid-term (2041-2060), and long-term (2081-2100) periods based on 24 CMIP6 models and three SSP scenarios (SSP1-2.6, SSP2-4.5 and SSP5-8.5). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.22 HERE]

8.4.2.4.1 South and Southeast Asian Monsoon

In AR5, South and Southeast Asian Monsoon (SAsiaM) precipitation was projected to increase by the end of the 21st century but with a weakening of the circulation, with high agreement across the CMIP5 models (Kitoh, 2017; Kitoh et al., 2013; Kulkarni et al., 2020; Menon et al., 2013; Sharmila et al., 2015; Sooraj et al., 2015). Since AR5, most studies have confirmed projected increases in South Asian monsoon precipitation (*high confidence*), while one high-resolution model (35 km in latitude/longitude) projects monsoon precipitation decreases during the 21st century following the RCP4.5 scenario (Krishnan et al., 2016).

Over South Asia, the moisture-bearing monsoon low-level jet is projected to shift northward in CMIP3 and CMIP5 models (Sandeep and Ajayamohan, 2015). Greater warming over the Asian land region compared to the ocean contributes to intensification of the monsoon low-level southwesterly winds and precipitation (Endo et al., 2018), even though the combined effect of upper and lower tropospheric warming makes the Asian monsoon circulation response rather complicated. A high resolution model projection, based on the RCP8.5 scenario, indicates that a northward shift of the low-level jet and associated weakening of the large-scale monsoon circulation can induce a large reduction in the genesis of monsoon low pressure systems by the late 21st century (Sandeep et al., 2018). Experiments with constant forcing indicate that at 1.5° and 2°C global warming levels, mean precipitation and monsoon extremes are projected to intensify in summer over India and South Asia (Chevuturi et al., 2018; Lee et al., 2018a) and that a 0.5°C difference would imply a 3% increase of precipitation (Chevuturi et al., 2018). CMIP5 models project an increase in short intense active days and decrease in long active days, with no significant change in the number of break spells for India (Sudeepkumar et al, 2018).

Future monsoon projections from CMIP6 models show an increase of SAsiaM precipitation across all the scenarios and across all the time frames (Figure 8.22) with the maximum increase at the end of the 21st century in SSP5-8.5 (Almazroui et al., 2020c; Chen et al., 2020e; Ha et al., 2020; Wang et al., 2020b). Table 8.2 confirms that changes in runoff and P-E over SAsiaM region are positive and largest in the higher emission scenarios considered, as in precipitation. On the other hand, changes in the ensemble mean for all the variables considered in the SSP1-1.9 scenario are negative for both mid and long term periods (Table 8.2). This is also consistently reflected in the spatial map of future precipitation changes (Figure 8.15). Different near-term projections of the SAsiaM may result given the diversity in the future aerosol emission pathways and policies for regulating air pollution (Wilcox et al., 2020). Additionally, near-term projections of SAsiaM precipitation are expected to be constrained by internal variability associated with the PDV (Huang et al., 2020b). CMIP6 models also indicate a lengthening of the summer monsoon over India by the end of the 21st century, at least in SSP2-4.5, with considerable inter-model spread in the projected late retreat (Ha et al. et al., 2020).

In summary, consistent with AR5, there is *high confidence* that SAsiaM precipitation is projected to increase during the 21st century in response to continued global warming across the CMIP6 higher emissions scenarios, mostly in the mid and long terms.

8.4.2.4.2 East Asian Monsoon

In AR5, the East Asian monsoon (EAsiaM) was projected to intensify in terms of precipitation, with an

ACCEPTED VERSION SUBJECT TO FINAL EDITING

earlier onset and longer duration of the summer season. Since AR5, there has been improved understanding of future projected changes in the EAsiaM.

CMIP5 projections indicated a possible intensification of the EAsiaM circulation during the 21st century, in addition to precipitation increase, although there is a lack of consensus on changes in the western North Pacific subtropical high, this is an important feature of the EAsiaM circulation (Kitoh, 2017). Furthermore, the EAsiaM precipitation enhancements in the CMIP5 projections are prominent over the southern part of the Baiu rainband by the late 21st century, with no significant changes in the Meiyu precipitation over central-eastern China (Horinouchi et al., 2019). It was also shown that the Baiu precipitation response in CMIP5 projections is accompanied by a southward retreat of the western North Pacific subtropical high and a southward shift of the East Asian subtropical jet (Horinouchi et al., 2019). According to the high-resolution MRI-AGCM global warming experiments, future summer precipitation could potentially increase on the southern side and decrease on the northern side of the present-day Baiu location in response to downward-motion tendencies which can offset the 'wet-gets-wetter' effect, but is subject to large model uncertainties (Ose, 2019). Future projections of land warming over the Eurasian continent (Endo et al., 2018) and intensified land-sea thermal contrast (Wang et al., 2016c; Tian et al., 2019) can potentially intensify the EAsiaM circulation during the 21st century. However, there are large uncertainties in projected water cycle changes over the region (Endo et al., 2018), mostly in the near-term because of uncertainties in future aerosol emission scenarios (Wilcox et al., 2020), as well as due to the interplay between internal variability and anthropogenic external forcing (Wang et al., 2021).

Interhemispheric mass exchange can act as a bridge connecting Southern Hemisphere circulation with EAsiaM rainfall, however this interhemispheric link is projected to weaken in a future warmer climate as seen from a CCSM4 projection using the RCP8.5 scenario (Yu et al., 2018). A comparison of 1.5°C and 2°C global warming levels reveals how a 0.5°C difference could result in precipitation enhancement over large areas of East Asia (Lee et al., 2018a; Liu et al., 2018b; Chen et al., 2019), with substantial increases in the frequency and intensity of extremes (Chevuturi et al., 2018; Li et al., 2019a). Future monsoon projections from the CMIP6 models show increase of EAsiaM precipitation across all the scenarios (Chen et al., 2020e), though with a large model spread mostly on the long-term and in the higher emission scenarios (Figure 8.22). Considering all the five scenarios used across the report, changes in precipitation, runoff and P-E over the EAsiaM are positive and become larger for highest emission scenarios and for the long term mean, except for the mid-term SSP1-1.9 scenario where the changes are close to zero or even negative (Table 8.2). Additionally, CMIP6 models confirm a projected increased length of the EAsiaM season due to early onset and late retreat (Ha et al., 2020).

In summary, despite the uncertainties in the monsoon circulation response in CMIP5 and CMIP6 models, there is *high confidence* that summer monsoon precipitation over East Asia will increase in the 21st century and *medium confidence* that the monsoon season will be longer.

8.4.2.4.3 West African Monsoon

AR5 concluded that projections of West African monsoon (WAfriM) rainfall are highly uncertain in CMIP3 and CMIP5 models, but still suggest a small delay and intensification in late wet season rains. Studies published since AR5 are broadly consistent with this assessment. CMIP6 models agree on statistically significant projected increases in rainfall in eastern-central Sahel and a decrease in the west for the end of the 21st century (Roehrig et al., 2013; Biasutti, 2019; Monerie et al., 2020). However, the magnitude of WAfriM projected precipitation depends on the convective parameterization used (Hill et al., 2017), and large uncertainties remain in WAfriM projections because of large inter-model spread, particularly over the western Sahel (Roehrig et al., 2013; Biasutti, 2019; Monerie et al., 2020). CMIP6 models show a general increase of WAfriM precipitation across all future scenarios but with a substantial model spread for the SSP5-8.5 scenario (Figure 8.22). This sensitivity arises from the combined and contrasting influences of anthropogenic greenhouse gas and aerosol forcing that affect WAfriM precipitation (particularly over the Sahel) directly and also indirectly through sub-tropical North Atlantic SST changes (Giannini and Kaplan, 2019). The large model spread and associated uncertainties in projected precipitation changes is reflected also in runoff and P-E changes (Table 8.2). Regional climate models (RCMs) ensembles (e.g., Klutse et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2018) agree with CMIP5 projected rainfall trends but some individual models show rainfall declines (e.g., Sylla et al., 2015; Akinsanola et al., 2018), highlighting the existing large uncertainties in RCMs WAfriM rainfall projections.

Changes in seasonality (see also Box 8.2) are projected with a later monsoon onset (*high confidence*) over the Sahel and a late cessation (*medium confidence*), suggesting a delayed wet season as a regional response to global GHG forcing (Biasutti, 2013; Akinsanola and Zhou, 2018; Dunning et al., 2018). Rainfall distribution is projected to be highly variable with a decrease in the number of rainy days in the western Sahel, consistent with an increase in consecutive dry days and a reduction in the number of growing season days (Cook and Vizy, 2012; Diallo et al., 2016). A decrease in the frequency but an increase in the intensity of very wet events is projected to be more pronounced over the Sahel than over Guinean coast, and also under higher emission scenarios (i.e. RCP8.5) (e.g., Sylla et al., 2015; Akinsanola et al., 2018).

In summary, post-AR5 studies and newly available CMIP6 results indicate projected rainfall increases in the eastern-central WAfriM region but decreases in the west (*high confidence*), with a delayed wet season (*medium confidence*). Overall, WAfriM summer precipitation is projected to increase during the 21st century but with larger uncertainty noted under high emission scenarios (*medium confidence*).

8.4.2.4.4 North American Monsoon

AR5 concluded that the North American Monsoon (NAmerM) will *likely* intensify in the future, even though there is *low agreement* among models. AR5 reported *medium confidence* that precipitation associated with the NAmerM will arrive later in the annual cycle and persist longer.

Since AR5, analyses of CMIP5 projections suggest little change in the overall amount of NAmerM precipitation in response to rising global surface temperature. However, significant declines are projected in the early monsoon season and increases in the late monsoon season, suggesting a shift in seasonality toward a delayed monsoon onset and demise (Cook et al., 2013). It is recognised that CMIP5 models are generally too coarsely-resolved to simulate the Gulf of California and the moisture surges associated with the NAmerM (Pascale et al., 2017). Under different RCPs, CMIP5 models tend to project a reduction in NAmerM precipitation but an increase in extreme precipitation events (Torres-Alavez et al., 2014; Bukovsky et al., 2015; Pascale et al., 2019). The almost unchanged or slight decrease in NAmerM total precipitation amount under global warming projections is at odds with paleoclimate records that suggest increased monsoon precipitation under past warm conditions (D'Agostino et al., 2019; Seth et al., 2019). However, there is *low agreement* on how those changes and the mechanisms that drive them are affected under different RCPs since most simulations are model-dependant (Cook and Seager, 2013; Geil et al., 2013; Pascale et al., 2019). Projections from six CMIP6 models show a shortening of the NAmerM under the SSP5-8.5 scenario due to earlier demises (Moon and Ha, 2020). In addition, CMIP6 projections show a decrease in NAmerM precipitation under SSP2-4.5 and SSP5-8.5 scenarios by the end of the 21st century with large inter-model spread (Figure 8.22). This result is also supported by the analysis of 31 CMIP6 models under the SSTP5-8.5 scenario for the 2080-2099 period (Almazroui et al., 2021). Non-linearities and uncertainties in the NAmerM projected changes are valid for many water cycle variables, like precipitation, runoff and P-E (Table 8.2).

In summary, there is *low agreement* on a projected decrease of NAmerM precipitation, however there is *high confidence* in delayed onsets and demises of the summer monsoon.

8.4.2.4.5 South American Monsoon

AR5 reported *medium confidence* that the South American Monsoon (SAmerM) overall precipitation will remain unchanged, and *medium confidence* in projections of extreme precipitation. AR5 also stated *high confidence* in the spatial expansion of the SAmerM, resulting from increased temperature and humidity.

Since AR5, some studies indicate that the SAmerM would experience changes in its seasonal cycle, with delayed monsoon onsets under increasing GHG emissions associated to different RCPs (Fu et al., 2013;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Reboita et al., 2014; Boisier et al., 2015; Pascale et al., 2016; Seth et al., 2019; Sena and Magnusdottir, 2020). In contrast, other studies indicate projected earlier onsets and delayed retreats of the SAmerM under the RCP8.5 scenario based on six CMIP5 models (Jones and Carvalho, 2013). These differences have been linked to the methodology used to determine monsoon timing, and sensitivity to the monsoon domain considered (Correa et al., 2021) (Section 8.3.2.4.5). Recent studies provide further evidence for the projection of delayed SAmerM onsets by the late 21 century (Sena and Magnusdottir, 2020). An analysis of six CMIP6 models under the SSP5-8.5 scenario confirm the projections of delayed SAmerM onsets by the end of the 21st century (Moon and Ha, 2020). In addition, projected changes in the intensity and length of the SAmerM season have been found to be model-dependent (Pascale et al., 2019). The analysis of CMIP5 projections of total monsoon rainfall indicate mixed signals in the Amazon and SAmerM regions (Jones and Carvalho, 2013; Marengo et al., 2014), with some studies suggesting increased summer precipitation in the core SAmerM region (Kitoh et al. et al., 2013; Seth et al., 2013). Dynamical downscaling of CMIP5 projections under the RCP4.5 and RCP8.5 scenarios with the Eta RCM suggests reductions of austral summer precipitation over the SAmerM region throughout the 21st century (Chou et al., 2014). Further analysis using 15 different CMIP6 models for the SSP2-4.5 scenario suggest reductions in total SAmerM rainfall (Wang et al., 2020a). However, other analyses of CMIP6 projections under different SSP scenarios do not report clear changes in the SAmerM precipitation throughout the 21st century (Chen et al., 2020e; Jin et al., 2020), Figure 8.22). Similar uncertainties for all the SSP scenarios used across the report are found for other water cycle variables, including runoff and P-E (Table 8.2). Furthermore, there is disagreement in projected extreme precipitation in the region, with some CMIP5-based studies suggest reductions (Marengo et al., 2014), while others indicate increases based on CMIP5 and CMIP6 models (Kitoh et al., 2013; Sena and Magnusdottir, 2020).

In summary, there is *high confidence* that the SAmerM will experience delayed onsets in association with increases in GHG. However, there is *low agreement* on the projected changes in terms of total precipitation of the South American summer monsoon season.

8.4.2.4.6 Australian and Maritime Continent Monsoon

AR5 concluded that projected changes in Australian and Maritime Continent Monsoon (AusMCM) rainfall and seasonality are uncertain in the CMIP5 models, with some projecting increases and others projecting decreases for the range of emissions scenarios. Models that perform better at simulating present day regional climate project little change or an increase in Australian monsoon rainfall (Jourdain et al., 2013; CSIRO and Bureau of Meteorology, 2015; Brown et al., 2016b). CMIP6 models project increased AusMCM precipitation in the 21st century but with a more robust signal in SSP2-4.5 and SSP5-8.5 rather than in lower emission scenarios (Figure 8.22). A reduced range of CMIP6 rainfall projections but continued disagreement on the sign of change is reported over Australia (Narsey et al., 2020).

The northern and eastern parts of the Maritime Continent have projected increases in rainfall in CMIP5 models (Siew et al., 2014), while there are projected decreases over Java, Sulawesi and southern parts of Borneo and Sumatra. Rainfall changes are correlated with the extent of warming in the western tropical Pacific in CMIP5 models (Brown et al., 2016b) but inter-model differences are also related to modelled large-scale zonal mean precipitation response in both CMIP5 and CMIP6 model ensembles (Narsey et al., 2020). Decomposition of projected rainfall changes indicates that the largest source of model uncertainty is associated with shifts in the spatial pattern of convection (Chadwick et al., 2013; Brown et al., 2016b). Uncertainties in capturing the spatial and temporal features of the Maritime Continent monsoon depend also on the horizontal resolution of coupled climate models (e.g. Jourdain et al., 2013).

The role of anthropogenic aerosol forcing in future projections of the Australian monsoon has been investigated for CMIP5 models (Dey et al., 2019); decreases in anthropogenic aerosol concentrations over the 21st century are expected to produce relatively greater warming in the Northern Hemisphere than Southern Hemisphere, favouring a northward shift of the tropical rain belt (e.g. Rotstayn et al., 2015).

There are some clear projected changes in the rainfall variability and extremes of the Australian monsoon. Rainfall variability in the Australian monsoon domain increases on time scales from daily to decadal in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

CMIP5 models (Brown et al., 2017), indicating either more intense wet days or more dry days or both. There is also a projected increase in the intensity of extreme rainfall but a reduction in the frequency of heavy rainfall days for the Australian monsoon (Dey et al., 2019). This is consistent with Moise et al. (2020), who found an increase in Australian monsoon active phase or 'burst' rainfall intensity but a reduction in the number of burst days and events.

Zhang et al. (2013) examined changes in Australian monsoon onset and duration in CMIP3 models and found model agreement on a delay in onset and shortened duration to the north of Australia, but less agreement over the interior of the continent. An updated study of CMIP5 models found similar mean changes with delayed onset and shortened duration, but substantial model disagreement (Zhang et al., 2016).

In summary, CMIP6 projections show an increase of AusMCM precipitation across all emission scenarios. There is strong model agreement on an increase in monsoon precipitation over the Maritime Continent while there is low agreement on the direction of change over northern Australia. There is a projected increase in rainfall variability over northern Australia, with increased intensity of rainfall during the active or 'burst' phase (*medium confidence*).

8.4.2.5 Tropical cyclones

Tropical cyclones (TCs) projections are primarily assessed in section 11.7.1.5. Here, we extend this analysis by assessing the implications of projected changes in tropical cyclones on the water cycle.

AR5 concluded that TC rainfall rate was *likely* to increase through the 21st century. Section 11.7.1.5 assesses that the average tropical cyclone rain-rate is projected to increase with warming (*high confidence*), and peak rain-rates are projected to increase at greater than the Clausius-Clapeyron scaling rate of 7% per 1°C of warming in some regions due to increased low-level moisture convergence (*medium confidence*). The increase in TC rainfall rate is explained by increased TC intensity resulting from increasing SSTs, and increased environmental water vapour (Chauvin et al., 2017; Liu et al., 2019b).

Consistent with the observed poleward migration of tropical cyclone activity (Kossin et al., 2014), in the Southern Hemisphere a larger proportion of storms are projected to decay south of 25°S at the end of the 21st century but with negligible changes in genesis latitude and storm duration for the Australian region (CSIRO and Bureau of Meteorology, 2015)(Sharmila and Walsh, 2018). An analysis of projections for North Pacific islands indicate that the maximum intensity of storms will increase but the number of tropical cyclones will decrease in some places, such as Guam and Kwajalein Atoll in the tropical northwestern Pacific, or remain the same in other regions like near Okinawa (Japan) or Oahu (Hawaii) (Widlansky et al., 2019). TC-induced storm tides affecting landfall in the Pearl River delta over South China are projected to increase by the end of the 21st century (Chen et al., 2020c)

In summary, there is *high confidence* that heavy precipitation associated with tropical cyclones is projected to increase, in response to well-understood processes related to increased low-level moisture convergence and environmental water vapour.

8.4.2.6 Stationary waves

AR5 did not provide an assessment of stationary wave projections as distinct from other related aspects of circulation, such as blocking, modes of variability, and storm tracks. Here we provide a brief assessment of stationary wave projections from the water cycle perspective, with the related circulation aspects considered separately in the following sections.

Several studies based on CMIP5 projections show changes in Northern Hemisphere winter stationary waves that increase precipitation over the west coast of North America and decrease it over the eastern Mediterranean and parts of southwestern North America (Neelin et al., 2013; Seager et al., 2014a, 2014b,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2019b; Simpson et al., 2016; Wills et al., 2019), although the underlying dynamics are not yet fully understood (Seager et al., 2019b; Wills et al., 2019). For the Northern Hemisphere winter global teleconnection pattern, the majority of the models analyzed in (Sandler and Harnik, 2020) project the development of a preferred longitudinal phasing for the pattern, but with strong disagreement among models over the details of the phasing and therefore the associated regional hydrologic impacts.

While the potential role of increasing hydrologic extremes with quasi-resonant stationary waves during Northern Hemisphere summer has received considerable attention (see Section 8.3.2.6), as yet there is no clear evidence in model projections that this variability will increase (Teng and Branstator, 2019). The influence of the Arctic on midlatitude circulation is assessed in Cross-Chapter Box 10.1, which reports that there is *low confidence* in the dominant contribution of Arctic warming compared to other drivers in future projections. Potential changes to the stratospheric polar vortex in CMIP5 models have a substantial influence on tropospheric stationary waves and associated hydrologic impacts in both the Northern (Zappa and Shepherd, 2017) and Southern Hemisphere (Mindlin et al., 2020). CMIP5 models have some important limitations in their representation of stationary waves (Lee and Black, 2013; Simpson et al., 2016; Garfinkel et al., 2020) and this aspect of CMIP6 models has not yet been comprehensively evaluated.

In summary, future changes in stationary waves may have an important influence on both the mean state and variability of the water cycle. Limitations in model representation, dynamical understanding, and the number of targeted studies on the topic currently constrain the assessment of future changes in stationary waves. Based on current knowledge, there is *low confidence* that projected changes in stationary wave activity will contribute to decreases of cold season precipitation over the eastern Mediterranean and increases over the west coast of North America.

8.4.2.7 Atmospheric blocking

In AR5, the increased ability of models to simulate blocking and higher agreement on projections led to an assessment with *medium confidence* that the frequency of Northern and Southern Hemisphere blocking will not increase, but future changes in blocking intensity and persistence were deemed uncertain (AR5 Chapter 14, ES and Box 14.2). Blocking influences precipitation (e.g., Trigo et al., 2004), flooding (e.g., Yamada et al., 2016), drought (e.g., Dong et al., 2018b), snow (e.g., García-Herrera and Barriopedro, 2006), and glacier melt (e.g., Hanna et al., 2013), and so is of broad importance to the water cycle in areas of blocking activity.

Blocking projections are assessed in this Report in Chapter 4 (Section 4.5.1.6), and model performance in simulating blocking is also discussed in Chapter 3 (Section 3.3.3.3). CMIP5 projections suggest a complex response in blocking frequencies with an eastward shift in Northern Hemisphere winter blocking, mid-latitude decreases in boreal summer except in eastern Europe-western Russia, and Southern Hemisphere decreases in the Pacific sector during austral spring and summer. CMIP6 projections (Figure. 4.28) show a notable decrease in blocking activity over Greenland and the North Pacific for the SSP3-7.0 and SSP5-8.5 scenarios. However, the continued large differences among current models as well as the sensitivity to blocking detection methods limits confidence in projected regional changes in blocking (see also Chapter 10, Section 10.3.3.3.1). The influence of blocking on multiple elements of the water cycle means that the uncertainty in blocking projections adds a corresponding layer of uncertainty to water cycle projections.

In summary, and despite recent improvements in the simulation of blocking, there is *limited evidence* in model projections of future changes, except for boreal winter over Greenland and the North Pacific where there is *high confidence* that blocking events are not expected to increase in the SSP3-7.0 and SSP5-8.5 scenarios. As with stationary waves, this adds uncertainty to mid-latitude water cycle projections at the regional scale.

8.4.2.8 Extratropical cyclones, storm tracks and atmospheric rivers

ACCEPTED VERSION SUBJECT TO FINAL EDITING

8.4.2.8.1 Extratropical cyclones and storm tracks

AR5 found that extratropical storms were expected to decrease in the Northern Hemisphere, but only by a few percent. Meanwhile, precipitation associated with extratropical storms was projected to increase due to thermodynamic increases in moisture but potentially also due to intensification from increased latent heat release. Latent heating is a strong influence on extratropical storms, so it is plausible that changes in precipitation and associated latent heating could affect extratropical storm intensity and thus precipitation (Zhang et al, 2019).

There is increased evidence that precipitation associated with individual extratropical storms is projected to increase, following thermodynamic drivers with negligible dynamic change (Yettella and Kay, 2017). Comparisons with reanalyses also support the projected increase in thermodynamic precipitation with little dynamic response for precipitation associated with extratropical storms (Li et al., 2014). There is *high confidence* that projected increases in precipitation associated with extratropical storms in over the Northern Hemisphere (Hawcroft et al., 2018; Kodama et al., 2019; Marciano et al., 2015; Michaelis et al., 2017; Pepler et al., 2016; Yettella and Kay, 2017; Zhang and Colle, 2017). A projected decrease in the number of extratropical cyclones over the Northern Hemisphere during the boreal summer in CMIP5 models was reported by (Chang et al., 2016) who related this decrease with a decrease in cloudiness and thus accentuating increased maximum temperatures. However, model spread was quite large, especially over North America, thus there is only *low confidence* in this seasonal signal.

In AR5, the Southern Hemisphere storm track was deemed *likely* to shift poleward, the North Pacific storm track *more likely than not* to shift poleward, while the North Atlantic storm track was *unlikely* to display any discernible changes. There was *low confidence* in regional storm track changes and the associated surface climate impacts, although a weakening of the Mediterranean storm track was a robust response of the models. Since AR5, the Southern Hemisphere mid-latitude storm track is projected to shift poleward and the westerlies are projected to strengthen over Australia (CSIRO and Bureau of Meteorology, 2015). Although thermodynamic effects were considered to be the most important factor in overall projections of increased mid-latitude precipitation, the general poleward shift in cyclogenesis and an enhanced latitudinal displacement of individual cyclones may play a role (Tamarin-Brodsky and Kaspi, 2017).

In the, several factors were identified as relevant to the uncertainties in projections of cyclone intensity, frequency, location of storm tracks and precipitation associated with ETCs. These include horizontal resolution, resolution of the stratosphere, and how changes in the Atlantic meridional overturning circulation (AMOC) were simulated. Since AR5, projections of extratropical cyclones and storm tracks have been examined further, largely confirming previous assessments. In particular, extratropical cyclone precipitation scales with the product of cyclone intensity (as measured by near-surface wind speed) and atmospheric moisture content (Pfahl and Sprenger, 2016). Booth et al. (2018) showed that the fraction of rainfall generated by the convection scheme in simulated extratropical cyclones is highly model- and resolution-dependent, which may be a source of uncertainty regarding their precipitation response to anthropogenic forcings. Also, increased moisture availability may increase the maximum intensity of individual storms while reducing the overall frequency as poleward energy transport becomes more efficient.

The role of temperature trends in influencing storm tracks has been further investigated, both in terms of upper tropospheric tropical warming (Zappa and Shepherd 2017) and lower tropospheric Arctic amplification (Wang et al., 2017), including the direct role of Arctic sea ice loss (Zappa et al., 2018), and the competition between their influences (Shaw et al, 2016). Physical linkages between Arctic amplification and changes in the mid-latitudes are uncertain, as discussed in Chapter 10 (Cross-Chapter Box 10.1). The remote and local SST influence has been further examined by Ciasto et al., (2016), who confirmed sensitivity of the storm tracks to the SST trends generated by the models and suggested that the primary greenhouse gas influence on storm track changes was indirect, acting through the greenhouse gas influence on SSTs. The importance of the stratospheric polar vortex in storm track changes has received more attention (Zappa and Shepherd 2017, Mindlin et al., 2020) and the anticipated recovery of the ozone layer further complicates the role of the stratosphere (Bracegirdle et al, 2020 ; Shaw et al., 2016).

Biases remain in cyclone locations, intensities, cloud features, and precipitation (Catto, 2016, Chang et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2016). Uncertainties in projected precipitation changes in many mid-latitude regions can be explained to a large degree by uncertainties in projected storm track or ETC changes. Multiple studies (Chang et al., 2013; Zappa et al., 2015; Chang, 2018) have shown strong relationships between model projected precipitation change in many regions and model projected change in storm track activity near that regions. While front frequency is well represented, frontal precipitation frequency is too high and the intensity is too low (Catto et al., 2015). Some of the bias in storm tracks appears to be related to limitations in model realization of blocking (Zappa et al. 2014). The CMIP6 generation of models has improved representation of storm tracks in both hemispheres (Bracegirdle et al., 2020; Harvey et al., 2020). Simulation of storm tracks and their associated precipitation generally improve with increasing resolution beyond that used in most current climate models (Barcikowska et al., 2018; Jung et al., 2006; Michaelis et al., 2017). In terms of projections, the decreases in cyclone occurrence over the Mediterranean were replicated in a higher resolution model (Raible et al., 2018).

The projected changes in storm tracks and the associated mechanisms have several important implications for water cycle projections. P-E changes in the Mediterranean, California and Chile are directly linked to storm track changes (Zappa et al., 2020). Where the storm tracks are robustly projected to shift (Southern Hemisphere, North Pacific) or weaken (Mediterranean), understanding the physical causes of the related changes in precipitation helps increase confidence in the projections. Understanding the competing influences provides context for why other regions do not exhibit a consistent signal and cautions against regional projections based on individual models. However, model bias and the need for relatively high resolution to reproduce the relevant dynamics is an important overall limit on confidence in current CMIP6 projections.

In summary, there is the *high confidence* that precipitation associated with extratropical storms will increase with global warming in most regions. The Southern Hemisphere storm track will *likely* shift poleward, the North Pacific storm track *more likely than not* will shift poleward, and the North Atlantic storm track is *unlikely* to have a simple poleward shift/ display any discernible changes. There is *low confidence* in regional storm track changes, although a weakening of the Mediterranean storm track is a robust response of the models.

8.4.2.8.2 Atmospheric Rivers

Atmospheric rivers were not assessed in AR5 but are important in the water cycle as they are linked to extreme rainfall, flooding, and changes in terrestrial water storage including melt and ablation of glaciers and snowpack (Section 8.2.2; 8.2.3.2). In a warming world, there is *high confidence* that thermodynamical increases in atmospheric water vapour ensure that atmospheric rivers will become wetter, hence stronger, and longer-lasting (Payne et al., 2020). This is clearly observed in several regional (Gao et al.,, 2015; Gershunov et al., 2019; Hagos et al., 2016; Payne and Magnusdottir, 2015; Ralph and Dettinger, 2011; Warner et al., 2015, Lavers et al., 2013) and in one global study (Espinoza et al., 2018) of atmospheric river activity in CMIP5 model projections. Lavers et al. (2015) indicate that integrated vapour transport under RCP 8.5 and 4.5 could increase, and consequently this thermodynamic response (O'Gorman, 2015) could affect mid-latitudes regions where orographic precipitation is important (Gershunov et al., 2019).

Under continued global warming, more intense moisture transport within atmospheric river events is projected to increase the magnitude of heavy precipitation events on the west coast of the United States (Lavers et al., 2015; Ralph and Dettinger, 2011; Warner and Mass, 2017), in western Europe (Lavers et al., 2015; Ralph et al., 2016; Ramos et al., 2016), and in east Asia (Kamae et al., 2019) (*very likely*). All CMIP5 models analysed agreed under a range of scenarios, except over the Iberian Peninsula (Ramos et al., 2016) where there is only *low confidence* in projected changes. Kamae et al. (2019) reported a 1% increase per degree Celsius warming in the frequency of atmospheric rivers affecting East Asia, but this is strongly affected by SST changes. Emerging evidence of possible regional changes due to dynamical factors are uncertain (Lavers et al., 2013; Gao and others, 2015; Payne and Magnusdottir, 2015). The frequency, magnitude and duration of atmospheric rivers making landfall along the North American west coast are projected to increase (Gershunov et al., 2019). In contrast, Espinoza et al. (2018) suggest that the number of atmospheric river events is projected to slightly decrease globally.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

In semi-arid regions where atmospheric rivers have historically been important and precipitation is mainly confined to the cold season, the contribution of atmospheric rivers to annual total precipitation may be expected to grow disproportionately. For example, in California decreases in precipitation frequency are projected as a result of fewer non-atmospheric river storms, while the projected increase in heavy and extreme precipitation events are almost entirely a result of increased atmospheric river activity (Gershunov et al., 2019). Interannual variability in precipitation amounts is projected to increase because of the overall decrease in the frequency of storms but a stronger dependence on extremes (Polade et al., 2014), particularly due to atmospheric rivers (Gershunov et al., 2019), especially where interaction with topography are important (Gershunov et al., 2019; Polade et al., 2014).

In summary, there is *high confidence* that the magnitude and duration of atmospheric rivers are projected to increase in future, leading to increased precipitation. This is projected to increase the intensity of heavy precipitation events on the west coast of the United States and in western Europe (*high confidence*).

8.4.2.9 Modes of climate variability and regional teleconnections

Following on from the assessment of projected changes in modes of climate variability (MoVs) and regional teleconnections (Section 4.5.3), here we assess their consequences for projected water cycle changes.

8.4.2.9.1 Tropical modes

CMIP6 projections indicate that the amplitude of ENSO (Annex IV.2.3) variability will not substantially change during the 21st century (*high confidence*) (Section 4.4.3.2). However, rainfall variability related to ENSO is projected to increase significantly by the second half of the 21st century, regardless of ENSO amplitude (Section 4.5.3.2). Regional precipitation variability associated with ENSO increases due to increases in atmospheric moisture, regardless of changes in ENSO variability itself (Pendergrass et al., 2017). In many regions, the magnitude of the projected changes related to ENSO is small compared with historical interannual variability (Bonfils et al., 2015; Power and Delage, 2018; Perry et al., 2019). Uncertainties in precipitation projections related to ENSO depend on internal variability associated with the mode (Section 8.5.2), hence the need to have relatively large ensembles (~15 members) to adequately estimate uncertainty (Deser et al., 2018; Maher et al., 2018a; Sun et al., 2018a; Zheng et al., 2018).

Even over regions with statistically significant simulated rainfall teleconnections during the historical period, CMIP5 models do not project clear changes (Perry et al., 2019). Nonetheless, CMIP5 models that realistically reproduce Indian summer monsoon rainfall indicate a strengthening of its relationship with ENSO in RCP8.5 projections, though the response is not consistent for different varieties of ENSO events (Roy et al., 2019). Inconsistent changes in the ENSO–Indian summer monsoon relationship in response to global warming in CMIP5 and CMIP6 models may be related to statistical issues rather than dynamical changes (Bódai et al., 2020; Haszpra et al., 2020). Over East Africa during the boreal spring and summer, ENSO teleconnections are projected to become stronger in the future (Endris et al., 2019). Meteorological drought consequences of each strong El Niño are projected to become more severe in the region (Rifai et al., 2019).

Indian Ocean Dipole (IOD, Annex IV.2.4) and Indian Ocean Basin (IOB, Annex IV.2.4) interactions with ENSO are expected to persist in the future (Section 4.5.3.3) but projected changes in the frequency and intensity of events remain uncertain (Hui and Zheng, 2018; Endris et al., 2019; McKenna et al., 2020). Climate extremes such as those associated with the extreme positive IOD event of 2019 are expected to occur more frequently under continued global warming (Cai et al., 2021). Projected changes in IOD teleconnections are linked to model performance in representing the IOD and its remote influence in the present climate, apparently dominated by a positive IOD event-like mean state (Wang et al., 2017a; Huang et al., 2019). Interactions between the IOD and the Indian Ocean mean state, via atmosphere-ocean feedbacks, can affect the behaviour of the IOD (Ng et al., 2018). In the eastern Horn of Africa, OND rainfall is projected to increase because of IOD-ENSO related SST changes in the Indo-Pacific region and associated

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Walker circulation changes (Endris et al., 2019).

Sensitivity studies generally project increases in Madden Julian Oscillation (MJO, Annex IV.2.8) precipitation amplitude in a warmer climate, with increases of up to 14% per °C of warming (Arnold et al., 2013, 2015; Caballero and Huber, 2013; Liu and Allan, 2013; Maloney and Xie, 2013; Schubert et al., 2013; Subramanian et al., 2014; Carlson and Caballero, 2016; Pritchard and Yang, 2016; Adames et al., 2017a; Wolding et al., 2017; Haertel, 2018). However, in CMIP5 models with realistic historical MJO behaviour, the precipitation amplitude over the Indo-Pacific warm pool region changes from -4% to +8% per °C in the RCP8.5 scenario relative to the end of the 20th Century (Bui and Maloney, 2018; Maloney et al., 2019). When simulated MJO precipitation amplitude increases with warming, the leading factor for such change is the intensification of the lower tropospheric vertical moisture gradient, that supports stronger vertical moisture advection per unit diabatic heating (Adames et al., 2017b, 2017a; Arnold et al., 2015; Wolding et al., 2017). In idealised simulations with constant carbon dioxide forcing with El Niño-like patterns, the MJO activity penetrates farther east into the central and east Pacific with increased warming (Subramanian et al., 2014; Adames et al., 2017a). Increased MJO convective variability in a warmer climate does not reflect into increased ability of the MJO to force the extratropics (Wolding et al., 2017).

In summary, even though there is *low confidence* in how the tropical MoVs will change in the future (Sections 4.3.3.2 and 4.5.3.3), their regional hydrological consequences, in terms of precipitation, are projected to intensify (*medium confidence*). For example, the ENSO influence on precipitation over the Indo–Pacific sector is projected to strengthen and shift eastward (*medium confidence*). The MJO is projected to intensify in a warmer climate, with increased associated precipitation (*medium confidence*).

8.4.2.9.2 Extra-tropical modes

CMIP6 projections indicate that the Northern Annular Mode (NAM, Annex IV.2.1) is expected to become more positive in winter throughout the 21st century in the SSP3-7.0 and SSP5-8.5 scenarios (Section 4.5.1). In the near-term, the Southern Annular Mode (SAM, Annex IV.2.2) is projected to become less positive than observed during the end of the 20th century during the austral summer in all SSPs scenarios (Section 4.3.3.1).

In the CMIP5 RCP8.5 scenario, increased amplitude and frequency of the North Atlantic Oscillation (NAO, Annex IV.2) during boreal winter (DJF) is associated with higher precipitation in northern Europe and lower precipitation in southern Europe (Tsanis and Tapoglou, 2019). However, large-ensembles analyses show how the NAO leads to significant uncertainty in future changes of regional climate (Section 8.5.2). For example, more than a 85% increase in precipitation is projected over northern Europe, western Russia and much of eastern North America, with similar decreasing resulting in drying over northwestern Africa and regions adjacent to the Mediterranean Sea (Deser et al., 2017).

In the Southern Hemisphere, the positive trend projected for the SAM in the CMIP5 RCP8.5 scenario appears to mitigate the wetting in the mid-to-high latitudes and the drying over the subtropics, but with strong seasonal dependence (Lim et al., 2016). Regional precipitation changes in South America, South Africa, Southern Australia and New Zealand are not well explained by changes in the SAM, but are related to broad-scale changes in north-south temperature gradients associated with enhanced warming of the tropical upper troposphere and strengthening of the stratospheric polar vortex (Mindlin et al., 2020).

In summary, projected changes in the intensity, frequency and phase of extratropical MoVs (see also Section 4.3 and 4.5) may amplify regional changes in precipitation and contribute to an increase in their intra-seasonal and interannual variability (*medium confidence*). Regionally, there are potentially significant precipitation and atmospheric circulation changes associated with changes in extratropical dynamics (*low confidence*).

8.5 What are the limits for projecting water cycle changes?

Understanding the limits to projecting water cycle changes are fundamental for refining climate and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

hydrological models needed to develop successful climate change adaptation strategies. Regional water cycle projections depend on a range of model-dependent responses (Section 8.5.1) and are also strongly influenced by internal variability, especially in the near term (Section 8.5.2) (Hawkins and Sutton, 2012; Rowell, 2012; Orlowsky and Seneviratne, 2013; Kent et al., 2015; Fatichi et al., 2016; Greve et al., 2018; Chegwidden et al., 2019). CMIP6 models show that different model responses to the same forcing scenario remain the main source of uncertainty for projected changes in regional precipitation (Figure 8.23) (Lehner et al., 2020). Section 8.5.3 assesses the potential for non-linear responses when shifting from low to high global warming levels (James et al., 2017; see also Section 8.4.2.4). While regional uncertainties related to downscaling methods (Section 10.3.3) and impact models (WGII Chapter 4) are not covered here, the added value of regional climate models is briefly discussed (Section 8.5.1.2.2) with a focus on water cycle changes.

[START FIGURE 8.23 HERE]

Figure 8.23: Geographical and zonal mean distribution of the percentage of variance explained by the three sources of uncertainty in CMIP6 projections of 20-year mean precipitation changes in 2021–2040 (top), 2041–2060 (middle) and 2081–2100 (bottom) relative to the 1995–2014 base period: internal climate variability (left), model response uncertainty (middle) and scenario uncertainty (right, considering four plausible concentration scenarios: SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5). Percentage numbers give the area-weighted global average value for each map. Right panels show the zonal mean fractions over both land and sea (solid lines) and over land only (dashed line). The figure was adapted from Fig.4a in (Lehner et al., 2020). The relative contributions of internal variability, models and emission scenarios to the total uncertainty depend on both region and time horizon. The scenario uncertainty is relatively low in near and mid-term time horizons while it increases in the long-term mostly over the high-latitudes. The model response uncertainty is the most influential factor across all time horizons. Internal variability also plays a key role in the near-term, especially in the subtropics. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.23 HERE]

8.5.1 Model uncertainties of relevance for the water cycle

Model response uncertainty is typically estimated as the inter-model spread (range) projected by a set of climate models for a given emission scenario. It is best estimated at the end of a high-emission scenario when internal variability has a limited contribution to total uncertainty (Figure 8.23). Even for aggregated quantities, like decadal-mean precipitation averaged over relatively large domains, model response uncertainty is substantial and can exceed scenario uncertainty (Hawkins and Sutton, 2011; Lehner et al., 2020). This can also be true for other water cycle variables such as soil moisture, runoff and streamflow at the regional scale, either derived directly from global climate models (GCMs) or produced by "offline" using global hydrological models (GHMs) driven by the same GCMs (Orlowsky and Seneviratne, 2013; Giuntoli et al., 2015, 2018; Chegwidden et al., 2019). Although some of the model response uncertainty is related to climatological biases (Grose et al., 2017; Li et al., 2017b; Lehner et al., 2019; Samanta et al., 2019), model biases are not the only way to assess the reliability of climate projections (cf. Box 4.1). Therefore, our focus here is on the representation of key processes that are not completely resolved in current-generation GCMs (Section 8.5.1.1) and on the model improvements associated with increased horizontal resolution (Section 8.5.1.2).

8.5.1.1 Fitness-for-purpose and poorly constrained key processes

AR5 Chapter 7 recognized that the simulation of clouds and precipitation remains challenging for state-of-the-art GCMs. Model development and evaluation have continued since AR5, with a particular emphasis on the representation of new model components, like interactive vegetation, aerosols and biogeochemical cycles. For example, the comparison of simulated tropical precipitation across three successive generations of CMIP models (including CMIP6) indicates overall little improvement for the summer monsoons, the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

double-ITCZ bias, the diurnal cycle and the frequency of precipitation (Fiedler et al., 2020). Some of these issues are related to inherent model limitations in three specific areas: atmospheric convection, cloud-aerosol interactions and land surface processes (ocean and cryosphere-related processes are addressed in Chapter 9). These limitations do not weaken the overall progress made in the large-scale simulation of present-day climate (FAQ 3.3, Section 3.3.2.2), even though the improvement of CMIP6 compared with CMIP5 models is limited (Figure 3.12) and is generally less systematic or obvious at the regional scale (e.g., Gusain et al., 2020; Monerie et al., 2020; Oudar et al., 2020). Instead, they call for a careful interpretation of hydrological projections with the full range of plausible outcomes, rather than only considering the most likely scenarios (Sutton, 2018, 2019).

8.5.1.1.1 Atmospheric convection

Moist convection is fundamental to the water cycle through its vertical transport of momentum, heat, and moisture across the atmosphere. It is particularly active in the tropics where it contributes to more than half of annual precipitation and to the development of severe weather events. Given limitations in computing resources, the current-generation GCMs cannot yet represent small-scale cloud processes and consequently shallow and deep convection is determined by sub-grid-scale parameterizations. While such parameterizations can be evaluated against field observations (e.g., Abdel-Lathif et al., 2018), it remains challenging to estimate convective entrainment that is valid for both shallow and deep convection (Zhang et al., 2016a). Comparisons between regional projections with explicit versus parameterized convection also highlight the limitations of parameterized convection for assessing climate change (Kendon et al., 2019; Jackson et al., 2020).

Atmospheric convection is particularly important for a realistic simulation of tropical precipitation intensities (Pendergrass and Hartmann, 2014a; Kendon et al., 2019). Many CMIP5 models produce rainfall at water vapour amounts lower than in observations (Takahashi, 2018), as well as too light and too frequent precipitation events (Sun et al., 2015; Trenberth et al., 2017). Such biases can be explained by a lack of convective inhibition (Rochetin et al., 2014a, 2014b) and by too much convective and too little non-convective precipitation (Chen and Dai, 2019). Tropical convection controls the amount of precipitable water simulated over the equatorial Indian Ocean, which has been identified as a key metric for differentiating model skill in simulating South Asian monsoon precipitation (Hagos et al., 2019). Many models have difficulty in adequately simulating the diurnal cycle of precipitation over land (Couvreux et al., 2015), the rainfall intensity distribution associated with the West African monsoon (Roehrig et al., 2013), and the intensity of tropical cyclones (Sections 10.3.3.4 and 11.7.1.3), phenomena for which atmospheric convection also plays a key role.

Since AR5, there have been improvements in the representation of convective clouds and related precipitation in GCMs. For instance, the drizzle issue (too light and too frequent rainfall events) has led to modifications in the deep convection triggering scheme (Rochetin et al., 2014b; Han et al., 2017; Wu et al., 2018a; Xie et al., 2018). Although high-resolution studies have highlighted these limitations, most GCMs still rely on a convective available potential energy (CAPE) closure which has been adapted to various cloud regimes (Bechtold et al., 2014; Han et al., 2017; Walters et al., 2017) or evaluated against convection-permitting models (CPMs) (Chen et al., 2020b). To increase the sensitivity of convection to tropospheric humidity, several models now include a representation of deep convective entrainment dependent on relative humidity (Bechtold et al., 2008; Han et al., 2017; Walters et al., 2017; Zhao et al., 2018c). Other efforts have focused on the improvement of shallow convection and low-level cloudiness due to their major contribution to uncertainty in climate sensitivity (Section 7.4.2.4). A cloud regime-based study however highlights an apparent disconnection between cloud and precipitation processes in GCMs (Tan et al., 2018), suggesting that a good representation of clouds does not lead to systematic improvement in simulated precipitation. A global simulation in which the parameterized convection is switched off shows a strong influence of parameterized convection on daily precipitation extremes (Maher et al., 2018b). Regional simulations at a 25km resolution suggest that an explicit deep convection can be beneficial even at such a relatively coarse resolution (Vergara-Temprado et al., 2020). Perturbed physics ensembles (PPE, Section 1.4.4) make it possible to identify parameters in the convection scheme that are most important in determining future precipitation changes (Bernstein and Neelin, 2016).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Since AR5, spatial aggregation of tropical convection has also received growing attention in both observational (Holloway et al., 2017) and modelling studies (Muller and Bony, 2015; Wing et al., 2017; Tan et al., 2018). The changing degree of convective organization was highlighted as a key mechanism for dynamic changes in extreme precipitation (Pendergrass, 2020a). Yet, convective parameterizations do not represent all aspects of mesoscale convective systems (Hourdin et al., 2013; Park et al., 2019). This is related to the complexity of mechanisms involved from synoptic to mesoscale dynamics, which are only partially resolved by models. Cloud-resolving models (CRMs, Section 8.5.1.2.2) represent a useful benchmark for improving the parameterization of mesoscale convective systems. Machine learning can also be used to parameterize moist convection after training the model with a conventional or a super parameterization scheme (Gentine et al., 2018; O'Gorman and Dwyer, 2018), but has not yet been used in the CMIP framework.

While some global modelling centres have reported progress in their parameterization of convection and in their simulation of seasonal, daily and sub-daily precipitation (e.g., Danabasoglu et al., 2020; Roehrig et al., 2020), CMIP6 models as a whole only show limited improvements in their simulation of the tropical precipitation climatology compared to CMIP5 (Fiedler et al., 2020; see also Figure 3.10). For instance, the double-ITCZ syndrome is still prominent (Tian and Dong, 2020) despite being reduced in some models (e.g., Qin and Lin, 2018). This systematic bias was shown to arise from atmospheric processes including cloud feedbacks (Tian, 2015; Dixit et al., 2018; Talib et al., 2018) and the SST threshold at which deep convection occurs in the tropics (Oueslati and Bellon, 2015; Xiang et al., 2017; Adam et al., 2018). Such biases can also arise from a too weak sensitivity of seasonal tropical precipitation to local SSTs compared with observations (Good et al., 2020). These biases are large enough to alter forced precipitation changes, and consequently limit our confidence in projected precipitation changes (Samanta et al., 2019; Aadhar and Mishra, 2020). Observational constraints can be used to narrow model response uncertainties (DeAngelis et al., 2015; Li et al., 2017b; Ham et al., 2018; Watanabe et al., 2018), although there is still no consensus that model selection or weighting is a reliable alternative to the 'one-model-one-vote' approach used in Section 8.4 (Box 4.1). The detrimental influence of model errors can also be mitigated by focusing on phenomena or events (Polson and Hegerl, 2017; Weller et al., 2017), implementing bias adjustment techniques (Section 10.2.3.2), or adopting a non-probabilistic storyline approach (Zappa and Shepherd, 2017).

In summary, since AR5 empirical convective parameterization schemes and associated precipitation biases have improved in some but not all global climate models. There is still *low confidence* in their ability to accurately simulate the spatio-temporal features of present-day precipitation, especially in the tropics where a double-ITCZ bias is still apparent in many models. While such biases limit the reliability of precipitation projections in some cases, there is currently only *medium confidence* that model selection or weighting is a better alternative to the one-model-one-vote approach (Box 4.1). Improved water cycle projections can be achieved by focusing on phenomena or weather events, such as a thermodynamic intensification of convective events (*high confidence*, Section 8.2.2.1), however accurate quantitative estimates are currently hampered by complex, model-dependent dynamical responses (Section 8.2.2.2).

8.5.1.1.2 Aerosol microphysical effects on clouds and precipitation

In AR5 Chapter 7, there was *low confidence* in the representation of cloud–aerosol interactions in climate models. Despite progresses in this field since AR5, cloud–aerosol interactions remain a major obstacle to understanding climate and severe weather (Varble, 2018). High aerosol concentrations have been observed to suppress rain in water clouds (Campos Braga et al., 2017; Fan et al., 2020). However, such aerosol effects are muted in GCMs, which tend to produce precipitation from shallow clouds too frequently at the expense of rain intensity (Suzuki et al., 2015; Jing et al., 2017). This arises from incomplete knowledge of how clouds adjust to aerosol primary effects such as cloud condensation nuclei (CCN). The adjustment occurs mainly as a dynamic response to the impacts of CCN on cloud drop size and number concentrations on precipitation-forming processes (Rosenfeld et al., 2008; Goren and Rosenfeld, 2014; Koren et al., 2014; Camponogara et al., 2018). Uncertainties are large for deep clouds, as their processes are much more complex and include also the impacts of aerosols on ice precipitation processes. Aerosols can substantially invigorate (Rosenfeld et al., 2008; Koren et al., 2014; Fan et al., 2018) and electrify (Thornton et al., 2017;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Wang et al., 2018b) deep tropical convective clouds. High-resolution atmospheric simulations suggest that high aerosol concentrations can increase environmental humidity by producing clouds that mix more condensed water into the surrounding air, which in turn favours large-scale ascent and strong convective events (Abbott and Cronin, 2021). Further assessment of uncertainties in aerosol-cloud interactions for shallow water clouds is provided in Section 7.3.3.2.

A major challenge in representing convective clouds and related precipitation events in GCMs is a lack of sophisticated cloud microphysics in convective parameterization schemes (e.g., Fan et al., 2016). Most of these schemes only include simple microphysical treatments, such as direct partition between cloud condensation and precipitation, and do not include advanced treatment of conversion among different types of hydrometeors. As such these schemes are unable to simulate microphysical cloud and precipitation responses to aerosol-related perturbations in cloud droplet concentration and ice crystals (see Box 8.1), or perturbations in thermodynamical states from global warming. Efforts have been made to include more advanced cloud microphysical treatment in cumulus parameterizations (Song and Zhang, 2011; Grell and Freitas, 2014; Berg et al., 2015) or to use explicit cloud microphysics schemes in climate models with a 'super parameterization' (Wang et al., 2015), which have been shown to improve the performance in simulating cloud properties and precipitation. However, few of these improvements have been incorporated into CMIP6 climate models so the projected precipitation response to anthropogenic perturbation may still be hindered by the inadequate microphysical treatment in cumulus parameterization (Smith et al., 2020).

In summary, there is still *low confidence* in the simulated influence of the aerosol microphysical effects on future precipitation changes.

8.5.1.1.3 Land surface processes

Land surface processes determine the partitioning of net surface radiation into sensible, latent and ground heat fluxes, the partitioning of precipitation into evapotranspiration and runoff, and the net terrestrial carbon flux at the Earth's surface. They are relevant for simulating the terrestrial water cycle responses to climate change, as well as the response to land use change (FAQ 8.1). Even basic land surface properties such as albedo (Terray et al., 2018) or the ratio of transpiration to total evaporation (Chang et al., 2018) still need to be improved in state-of-the-art coupled GCMs. Runoff sensitivities are also not well constrained in these models, which display a large spread for the present-day climate, influencing simulated changes under global warming (Lehner et al., 2019). Earth System Models (ESMs) incorporate some combined biophysical and biogeochemical processes to a limited extent, and many relevant processes about how plants and soils interactively respond to climate changes are yet to be considered (e.g., Liu et al., 2020). Consequently, land surface processes and their atmospheric coupling contribute to the range in water cycle projections (Jia et al., 2020).

Since AR5, development of new and existing processes in land surface models (LSMs) have been evaluated. These include soil freezing and permafrost (Vergnes et al., 2014; Chadburn et al., 2015; Yang et al., 2018a; Gao et al., 2019), soil and snow hydrology (Brunke et al., 2016; Decharme et al., 2016), glaciers (Shannon et al., 2019), surface waters and rivers (Decharme et al., 2012), as well as vegetation (Bartlett and Verseghy, 2015; Betts et al., 2015; Knauer et al., 2015; Tang et al., 2015) and the representation of hydraulic gradients throughout the soil-plant-atmosphere continuum (Bonan et al., 2014). Such land surface model developments have led to significant improvements in global off-line hydrological simulations driven by observed atmospheric forcings (e.g., Li et al., 2017a; Decharme et al., 2019).

Progress in the representation of land surface heterogeneity has been made, in the form of improved mapping of root zone storage capacity (Wang-Erlandsson et al., 2016), improved vegetation stand, disturbance and fire dynamics (Li et al., 2013a; Fisher et al., 2018; Haverd et al., 2018; Yue et al., 2018; Zou et al., 2019), better representation of urban surfaces (Box 10.3), and the explicit representation of inland water bodies (Gu et al., 2015; Verseghy and MacKay, 2017). The representation of realistic snow and vegetation cover significantly affects the simulation of the land surface energy and water budgets at multiple time-scales (Loranty et al., 2014; Bartlett and Verseghy, 2015; Thackeray et al., 2015; Qiu et al., 2016; Thackeray and Fletcher, 2016; Wang et al., 2016a; Alessandri et al., 2017). Groundwater remains inadequately represented

ACCEPTED VERSION SUBJECT TO FINAL EDITING

in many models, which limits our current understanding of the two-way interactions between groundwater and the rest of the hydrologic cycle (Taylor et al., 2013b; Leng et al., 2014; Vergnes et al., 2014; Pokhrel et al., 2015; Maxwell and Condon, 2016; Collins, 2017; Scanlon et al., 2018; Condon et al., 2020). Land management exerts an increasing influence on the water cycle (Abbott et al., 2019) whose representation in the current-generation climate models is generally incomplete (Section 10.3.3.7.2).

Aside from land surface models (LSMs), global hydrological models (GHMs) have been further developed for off-line simulations of the hydrological impacts of both climate change and water management (Cisneros et al., 2014; Schewe et al., 2014; Döll et al., 2016, 2018b, Pokhrel et al., 2016, 2017; Veldkamp et al., 2018). GHMs can equal or outweigh the contribution of GCMs to uncertainties in hydrological projections at the regional scale (Giuntoli et al., 2015). Historical GHM simulations are currently not sufficient to improve regional water cycle projections, due to modelling uncertainties in both the driving GCMs and land surface hydrology (Pechlivanidis et al., 2017; Samaniego et al., 2017; Hattermann et al., 2018; Krysanova et al., 2018). Biophysical vegetation processes are still not accounted for in many GHMs, which may lead to inadequate projections of terrestrial runoff and water resources. However, hydrological models that do simulate these effects often disagree (Prudhomme et al., 2014), so do not necessarily provide the added value of a more sophisticated representation of vegetation processes and land surface conditions (Döll et al., 2016).

Since AR5, there has been increasing recognition of the need to better understand the role of land–atmosphere coupling and related feedbacks (Joetzjer et al., 2014; Berg et al., 2016; Catalano et al., 2016; Berg and Sheffield, 2018a; Santanello et al., 2018). This has led to the development of dedicated field campaigns (Song et al., 2016; Phillips et al., 2017; Dirmeyer et al., 2018), remotely sensed observations (Ferguson and Wood, 2011; Roundy and Santanello, 2017), and tailored diagnostics (Tawfik et al., 2015a, 2015b, Miralles et al., 2016, 2019; Dirmeyer and Halder, 2017). Dynamic vegetation models have been introduced in global ESMs but they need further evaluation (Medlyn et al., 2015; Prentice et al., 2015; Cantú et al., 2018; Franks et al., 2018) to provide valuable information on potential vegetation feedbacks. Plant migration and mortality, increased disturbances from wild fires, insects and extreme events, interactive nitrogen cycle, or the impact of increased levels of tropospheric ozone are often ignored or poorly represented in the current-generation of ESMs (Bonan and Doney, 2018; Fisher et al., 2018).

The physiological response of plants to increasing atmospheric CO_2 is generally accounted for, but only using empirical models of stomatal conductance that are characterized by a single critical parameter of intrinsic water-use efficiency (Franks et al., 2017, 2018). This reflects a lack of structural diversity and caution about the consensus of the photosynthesis response to increasing CO_2 (Knauer et al., 2015; Huang et al., 2016), which has implications for the ability of the current-generation models to account for uncertainty in future evapotranspiration changes. Most CMIP5 models underestimate the ratio of plant transpiration to total terrestrial evapotranspiration, which may suggest that they also underestimate the impact of plant physiology on the water cycle (Lian et al., 2018). Plant hydraulics are not explicitly considered in many land surface models, which may lead to an underestimation of the influence of the increasing atmospheric moisture stress on plant transpiration under climate change (Massmann et al., 2019; Grossiord et al., 2020; Liu et al., 2020c). Most ESMs underestimate the water use efficiency measured at many sites and, consequently overestimate the ratio of evapotranspiration to precipitation (Li et al., 2018a).

In summary, since AR5 substantial advances have been made in the representation of land surface processes in current-generation Earth System Models (ESMs). Off-line hydrological models allow the application of bias-adjusted atmospheric forcings, but there is *low confidence* of an improved response compared to coupled climate models, given their inherent limitations (Box 10.2). While improvements in the representation of complex land surface feedbacks relevant to the water cycle are needed, there is currently *low confidence* that they will substantially improve of water cycle projections.

8.5.1.2 Added value of increased horizontal model resolution

Coarse spatial resolution of climate models has often been considered a key limitation in global climate projections (Di Luca et al., 2015; Roberts et al., 2018). Proposed and tested solutions include a uniform or

ACCEPTED VERSION SUBJECT TO FINAL EDITING

regional increase in the resolution of GCMs, or the use of regional climate models (RCMs). The increase in computing resources has also led to the development of convection-permitting models (Prein et al., 2015), which have been integrated over larger domains, but are still unsuitable for CMIP simulations. Statistical downscaling tools are also widely used to generate fine-scale regional climate information necessary for climate impacts and adaptation studies. A comprehensive assessment of the added value of increased spatial resolution and of the benefits and shortcomings of statistical downscaling tools are addressed in Chapter 10 (Section 10.3.3).

8.5.1.2.1 High-resolution global climate models

Since AR5, horizontal resolution has increased in most global climate models, which has led to several improvements in the simulation of the water cycle (see also Section 10.3.1.1), not only in areas with steep or complex orography, but also over the tropical oceans and within the North Pacific and North Atlantic storm tracks (Piazza et al., 2016; Roberts et al., 2018; Bui et al., 2019; Chen and Dai, 2019; Vannière et al., 2019). Yet, the added value of higher resolution global climate models is not systematic (Johnson et al., 2016; Ogata et al., 2017; Huang et al., 2018a; Mahajan et al., 2018; Vannière et al., 2019) and needs careful assessment (Haarsma et al., 2016; Caldwell et al., 2019). Several AGCM studies suggest that increased spatial resolution leads to better simulation of the atmospheric moisture transport from ocean to land, the geographical distribution of annual mean precipitation (Demory et al., 2014), and the frequency distribution of daily precipitation intensities (Zhang et al., 2016c; Chen and Dai, 2019) including extremes in many (Jacob et al., 2014; Westra et al., 2014) but not all cases (Bador et al., 2020).

Part of the improvement in simulated precipitation accuracy is related to improved simulation of the frequency and/or mean intensity of tropical (Roberts et al., 2015; Walsh et al., 2015) and extratropical (Hawcroft et al., 2016) cyclones. Idealized regional experiments also show that the North Atlantic storm-track response to global warming can be amplified in higher resolution models (Willison et al., 2015). Increased atmospheric horizontal resolution can be also important for simulating Northern Hemisphere blockings (Davini et al., 2017; Schiemann et al., 2017) and synoptic features of the East Asian summer monsoon (Yao et al., 2017; Kusunoki, 2018). Variable resolution based on grid stretching may be a valuable alternative for simulating regional phenomena like monsoons (P Sabin et al., 2013; Krishnan et al., 2016) or tropical cyclones (Harris et al., 2016; Chauvin et al., 2017), while avoiding inconsistencies in the forcings or physics that can be found in RCMs driven by GCMs (Boé et al., 2020; Tapiador et al., 2020).

Increasing horizontal model resolution in CMIP5 and CMIP6 models leads to a systematic increase in global mean precipitation, enhanced moisture advection to land in close connection with increased orographic precipitation, and a partial reduction of the long-standing double ITCZ bias (Demory et al., 2014; Caldwell et al., 2019; Vannière et al., 2019). Recent studies based on HighResMIP simulations (Haarsma et al., 2016) confirm the added value of increased horizontal resolution (at least 50 km in the atmosphere and 25 km in the ocean) for the simulation of tropical (Roberts et al., 2020) and extratropical cyclones (Priestley et al., 2020). CMIP6 model biases in annual mean precipitation are only slightly reduced at higher resolution (Figure 3.10).

High resolution representation of the land surface is also important for simulating many features of the terrestrial water cycle, such as orographic precipitation, snow, runoff and streamflow in complex topography areas (Zhao and Li, 2015). However, the added value may be easier to assess in off-line rather than online land surface simulations (Döll et al., 2016) given the possible use of bias-corrected atmospheric forcings. Off-line high-resolution GHMs are routinely used to monitor water resources or to assess the hydrological impacts of bias-adjusted global climate projections (Davie et al., 2013; Huang et al., 2017, 2018b). Yet, the development and calibration of 'hyper-resolution' hydrological models, with grid cells of typically 100m to 1km, raises a number of issues given the lack of comprehensive surface or subsurface information (Bierkens et al., 2015) and the lack of coupling with the atmosphere (Berg and Sheffield, 2018a).

In summary, there is *high confidence* that increasing horizontal resolution in GCMs can reduce a number of systematic model errors of relevance for the water cycle, including synoptic circulation and the accuracy of daily precipitation projections. High-resolution GCMs and GHMs provide improved representation of land surfaces, including topography, vegetation and land use change, which are required to accurately simulate

ACCEPTED VERSION SUBJECT TO FINAL EDITING

changes in the terrestrial water cycle. However, there is *low confidence* that the higher horizontal resolution simulations currently available provide more accurate projections of the large-scale features of the water cycle.

8.5.1.2.2 Regional Climate Models and Convective Permitting Models

Regional Climate Models (RCMs) are used to dynamically downscale global model simulations for a particular region (usually at a spatial resolution in the order of 10 to 50 km) (see Section 10.3.3). AR5 reported that RCMs are useful for regions with variable topography and for small-scale phenomena, however inherit biases from their driving GCMs and thus may lack physical consistency with them. Since AR5, the application of RCMs has largely increased due to international model inter-comparison projects such as CLARIS-LPB (Sánchez et al., 2015). Many studies have focused on present-day climatological precipitation, showing with *high confidence* improvements in its monthly to seasonal accumulation and spatial distribution (Dosio et al., 2015; Giorgi et al., 2016; Bozkurt et al., 2019; Falco et al., 2019; Di Virgilio et al., 2020), although the modelling of precipitation remains the 'Achilles heel' of both GCMs and RCMs and should be considered cautiously when informing regional climate change adaptation strategies (Tapiador et al., 2019a).

Regional Convective Permitting Models (CPMs), typically run at a resolution less than 10 km, have been implemented over increasingly large domains. Compared to models with parameterized convection (Section 8.5.1.1.1), they generally show improved simulation of key features of the water cycle such as orographic precipitation, sea-breeze dynamics, the diurnal cycle in precipitation, soil-moisture precipitation feedbacks, daily precipitation persistence, sub-daily to daily precipitation intensities and related extremes (Birch et al., 2015; Prein et al., 2015; Willetts et al., 2017; Kendon et al., 2017; Leutwyler et al., 2017; Hohenegger and Stevens, 2018; Berthou et al., 2019b; Takahashi and Polcher, 2019; Fumière et al., 2020; Scaff et al., 2020; Caillaud et al., 2021; see also Section 8.2.3.2). A growing number of studies have also assessed the potential added value of using CPMs for regional climate projections (Ban et al., 2015; Giorgi et al., 2016; Fosser et al., 2017; Kendon et al., 2017, 2019; Liu et al., 2017; Rasmussen et al., 2017; Lenderink et al., 2019; see also Atlas 5.6.3). Although projected changes in rainfall occurrence in CPMs are broadly and qualitatively consistent with the results of GCMs and RCMs (Kendon et al., 2017), there is a tendency towards stronger changes in both wet and dry extremes (Berthou et al., 2019a; Kendon et al., 2019; Lenderink et al., 2019; Finney et al., 2020a). While both GCMs and RCMs project an overall decrease in summer precipitation over the Alps, RCMs simulate an increase over the high Alpine elevations that is not present in the global simulations (Giorgi et al., 2016).

Recent studies based on both GCMs and CPMs indicate that both CAPE and convective inhibition will increase in a warmer climate (Chen et al., 2020; see also Section 8.2.3.2), consistent with a shift from moderate to less frequent but stronger convective events (Rasmussen et al., 2017). If underestimated by models with parameterized convection, such a mechanism could explain the underestimation of both projected increase in precipitation extremes (Borodina et al., 2017; Yin et al., 2018) and land surface drying (Douville and Plazzotta, 2017) in the extratropics. CMIP5 models with a larger increase in extreme precipitation also exhibit larger declines or smaller increases in light-moderate events (Thackeray et al., 2018).

In summary, there is *high confidence* that dynamical downscaling using limited area models adds value in simulating precipitation and related water cycle processes at the regional scale, especially in complex orography areas (see also Section 10.3.3.5.1). There is *high confidence* that the explicit simulation of atmospheric convection can improve the representation of weather phenomena, including the life cycle of convective storms and related precipitation extremes. Even with an improved simulation of small-scale processes, there is only *medium confidence* that there will be an improvement in RCM-based water cycle projections as they rely on GCM boundary conditions.

8.5.2 Role of internal variability and volcanic forcing

Beyond modelling uncertainties, internal variability and unpredictable natural forcings may also lower the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

degree of confidence in projected water cycle changes, especially in the near-term (2021-2040) and regional-scale projections (Hawkins and Sutton, 2011; Kent et al., 2015; Thompson et al., 2015; Fatichi et al., 2016; McKinnon and Deser, 2018; Chen and Brissette, 2019; Lehner et al., 2020). Although there is *low confidence* that the main modes of climate variability (Annex IV) are altered in a warmer climate (Sections 4.4.3 and 4.5.3), increasing contrast between wet and dry weather regimes (Section 8.2.2.1) will amplify their influence on water cycle variability (Section 8.4.2.9) and therefore contribute to uncertainties in near-term precipitation changes (Figure 8.23). The role of internal variability as source of uncertainties in regional climate projections is assessed in Section 10.3.4.3. Here we assess the role of internal variability in influencing water cycle projections using paleoclimate reconstructions, preindustrial model simulations, and large single model ensembles (Section 8.5.2.1). Implications for the predictability of near-term water cycle changes are specifically assessed, as they show significant but model-dependent regional hydrological fingerprints over land (Section 8.5.2.2). The role of volcanic eruptions is also briefly assessed in terms of consequences and uncertainties in water cycle projections (Section 8.5.2.3).

8.5.2.1 Quantification of water cycle internal variability

Estimating internal variability is an important challenge in the assessment of human-induced changes in the water cycle since its magnitude and range of variability can exceed the anthropogenic signal, at least at the regional scale and for near-term projections or low-emission scenarios (Deser et al., 2012; Shepherd, 2014; Xie et al., 2015; Sarojini et al., 2016; Dai and Bloecker, 2019; Lehner et al., 2020) (Section 4.4.1.4, 8.4.2.9). Underestimating internal variability in models may result in the overestimation of anthropogenic climate change because the 'noise' in the signal-to-noise ratio is underestimated (Knutson and Zeng et al., 2018). There is *medium confidence* that this underestimation affects global water cycle projections, for instance, in terms of drought persistence and severity in the southwestern United States, eastern Australia, southern Africa, the Mediterranean, the southern Amazon basin and China (Ault et al., 2014; Cook et al., 2018; Gu et al., 2018). In CMIP6 models, the uncertainty in future projections of 20-year mean precipitation changes attributable to internal variability ranges from 41% in the near-term (2021-2040) to 5% in the long-term (2081-2100) (Figure 8.23). For decadal-mean precipitation changes, the relative contribution of internal variability is even larger when using large ensembles (Lehner et al., 2020).

Over the 20th century, CMIP5 models show a realistic magnitude of decadal precipitation variability, if not a slight overestimation in some regions (Knutson and Zeng, 2018). However, the relatively short and human-influenced instrumental record limits our ability to quantify the magnitude of internal variability in the water cycle, particularly over long timescales (decadal and beyond). Global extended reanalyses (Section 1.5.2) have been used to derive long-term variability in the regional water cycle components (Caillouet et al., 2017), merged with historical meteorological and hydrological local observations (Bonnet et al., 2017; Devers et al., 2020). Specific assessment of these types of methodology and related uncertainties is provided in Chapter 10 (Sections 10.2 and 10.3). Paleoclimate archives (tree rings, corals, ice core, speleothems, lake and ocean sediments) provide extended reconstructions of key water cycle metrics and large-scale circulation features. Some studies have suggested that CMIP5 models underestimate internal variability at decadal and longer timescales, and therefore may be missing important processes in the climate system (Ault et al., 2012, 2013; Bunde et al., 2013; Franke et al., 2013; Cheung et al., 2017; Hope et al., 2017; Kravtsov, 2017; Cassou et al., 2018). However, recent assessments using paleoclimate records have found that CMIP5 models are able to reproduce decadal-to-centennial variability, including the severity, persistence and spatial extent of megadroughts (Coats et al., 2015; Stevenson et al., 2015; PAGES Hydro2K Consortium, 2017), once signal reddening (autocorrelation) in proxy archives is accounted for (Dee et al., 2017; PAGES Hydro2K Consortium, 2017). Implementation of proxy system models, i.e., functions that transform model variables into proxy units, has reduced model-proxy disagreement, although some differences in the magnitude of internal variability remain, particularly at centennial timescales (Dee et al., 2017; Parsons et al., 2017). It is unclear whether remaining discrepancies represent limitations of the climate models, or limitations of the proxy system models. Therefore, there is *medium to high confidence* (i.e., depending on the region) that climate models do not underestimate water cycle internal variability.

The mechanisms driving internal variability in the water cycle in climate model simulations varies. While

ACCEPTED VERSION SUBJECT TO FINAL EDITING

models indicate that cool SSTs in the eastern tropical Pacific (La Niña or the cool phase of the PDO) are associated with drought in southwestern North America, they also show that atmospheric internal variability may be a more prominent driver (Coats et al., 2015, 2016; Stevenson et al., 2015; Parsons et al., 2018). CMIP5–PMIP3 last millennium simulations reproduce the observed negative correlation between eastern Australian rainfall and the central equatorial Pacific SSTs with varying skill, and also display periods when the ENSO teleconnection weakens substantially for several decades (Brown et al., 2016a). Differences in simulated internal variability have been found to be responsible for the inter-model spread in predicted shifts in subtropical dry zones for a given shift in the Hadley cell (Seviour et al., 2018). CMIP5 models show that both internal variability and anthropogenic forcings are responsible for the drying over the South Atlantic Convergence Zone region, though with large uncertainties (Zilli and Carvalho, 2021). Moreover, the detection of the anthropogenic forcing on the South Atlantic Convergence Zone is strongly dependent on the characterization of model internal variability (Talento and Barreiro, 2012).

Beyond the tropics, North Pacific decadal variability (Annex IV.2.6, 2.4.5, 3.7.6) exerts a strong modulation of extratropical ENSO teleconnections, but also influences low-frequency variability of the Walker circulation, which is underestimated by most CMIP5 models (England et al., 2014). Atlantic Multidecadal Variability (Annex IV.2.7, 2.4.6, 3.7.7) teleconnections show a high model spread among CMIP5 models, both in terms of persistence and spatial coherence (Qasmi et al., 2017), which has potential consequences for the water cycle variability simulated over Europe. For example, internal variability will continue to play an important role in the variability of river flows over France in coming decades *(medium confidence)* (Giuntoli et al., 2013; Boé and Habets, 2014; Bonnet et al., 2017).

Ensembles of atmosphere-only simulations driven by observed or reconstructed SST are useful for evaluating the ability of models to capture the circulation and/or precipitation variability observed over the historical period (Zhou et al., 2016; Deng et al., 2018; Douville et al., 2019). However, limitations of such AGCM-based attribution methods, i.e. related to the lack of air–sea interactions in the response, may lead to erroneous attribution conclusions in some regions for local circulation and mean and extreme precipitation (Dong et al., 2017). Other methods to measure the portion of precipitation variability include the partitioning into dynamical versus thermodynamical components (Saffioti et al., 2016; Fereday et al., 2018; Lehner et al., 2018), the analysis of variance (Dong et al., 2018a) and direct characterization of stochastic weather-noise (Short Gianotti et al., 2014).

Single model initial conditions large ensembles (SMILEs) are a powerful tool for estimating the magnitude of internal variability in historical and future climates (Section 1.4.4). Using SMILEs, it has been shown, for example, that internal NAO variability imparts substantial uncertainty to future changes in European precipitation (Deser et al., 2017; Figure 8.24). For the South Asian summer monsoon, internal variability can overshadow the forced monsoon rainfall trend, thereby increasing near-term projection uncertainties (Huang et al., 2020b). Specific regional applications of the use of large ensembles are further assessed in Sections 10.3.4.3 and 10.3.4.4.

Since AR5, SMILEs have helped quantify the time of emergence of climate change signals (see Sections 1.4.2.2 and 10.4.3). Results from SMILEs indicate that by 2000–2009 (compared to 1950–1999), simulated anthropogenic shifts in mean annual precipitation already emerged over 36-41% of the globe including high latitudes (Frankcombe et al., 2018; Kumar and Ganguly, 2018), the eastern subtropical oceans, and the tropics (Zhang and Delworth, 2018). By 2050 (2100), more than 60% (85%) of the globe is projected to show detectable anthropogenic shifts in mean annual precipitation (Zhang and Delworth, 2018). Other SMILE results for the 1950-2100 period (Kay et al., 2015; Sigmond and Fyfe, 2016) indicate that internal variability can obscure the detection of the anthropogenic hydroclimatic signal until the middle to late 21st century in many parts of the world for both mean and extreme precipitation (Martel et al., 2018; Dai and Bloecker, 2019). A common finding is that changes in the characteristics of wet extreme events will emerge earlier than changes in average conditions (Gaetani et al., 2020; Hawkins et al., 2020; Kusunoki et al., 2020). An assessment of the methods used to estimate time of emergence is presented in Chapter 10 (Section 10.3.4.3). For specific regional examples of climate change attribution and emergence of anthropogenic signal, see Section 10.4.2.

[START FIGURE 8.24 HERE]

Figure 8.24: Impact of the North Atlantic Oscillation (NAO) on 2016–2045 climate trends. (a) Regressions of winter sea level pressure (SLP) and precipitation trends upon the normalized leading principal component (PC)of winter SLP trends in the CESM1 Large Ensemble, multiplied by two to correspond to a two standard deviation anomaly of the PC (as internal climate variability component); (b) CESM1 ensemble-mean winter SLP and precipitation trends (as forced climate variability component); (c) b – a (forced minus internal climate variability component); (d) b + a (forced plus internal climate variability component). Precipitation in colour shading (mm/day per 30 years) and SLP in contours (interval = 1 hPa per 30 years with negative values dashed) (Adapted from Deser et al., 2017). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.24 HERE]

In summary, there is *medium confidence* that climate models reproduce the general magnitude and character of internal variability that influences water cycle variables. There is *high confidence* that internal variability will continue to be a major source of uncertainty, at least for near-term water cycle projections at the regional scale. There is *low confidence* in the region-dependent time of emergence of water cycle changes (see also Section 10.4.3), but there is *medium confidence* that changes in wet extreme events will emerge earlier than changes in average conditions.

8.5.2.2 Implications for near-term water cycle projections

Adapting water resource management in the face of climate change will greatly benefit from improved prediction of land surface hydrology at the decadal timescale. Climate predictions (Section 1.4.4) differ from climate projections by constraining the initial state of the slow components of the climate system (i.e. the ocean, the cryosphere and the terrestrial hydrology) as well as volcanic aerosols and ozone depleting substances with observations. Anthropogenic and natural radiative forcing and low-frequency modes of variability (e.g., AMV and PDV, Annex IV.2.7 and IV.2.6) suggest the possible predictability of climate in the first decade or so of the 21st century, in addition to the projected response to the anthropogenic forcing (Sections 4.2.3 and 4.4.1.3).

In AR5, decadal prediction of precipitation over some land areas showed improved skill due to specified radiative forcing, with almost no added value from ocean initialization. Since AR5, more studies have been devoted to understanding the potential or effective water cycle predictability related to ocean multi-decadal variability. Decadal hindcast experiments based on large ensembles highlight increasing skill scores in annual mean precipitation 3-7 year ahead, at least over the Sahel and Europe (Yeager et al., 2018). There is relatively high predictability of the AMV impacts over the Mediterranean basin, central Asia and the Americas (from United States to northern South America) during boreal summer, but in boreal winter the signal-to-noise ratio shows only weak predictability over land (Yamamoto and Palter, 2016; Ruprich-Robert et al., 2017). The link between South Asian summer monsoon changes and the AMOC and the decadal variability in the Pacific Ocean open the possibility of increased predictability for the near future (Kushnir et al., 2017; Huang et al., 2020c; Sandeep et al., 2020).

The additional skill associated with the initialization of the cryosphere and the land surface has received limited attention. However, there is observational evidence that oceanic decadal variations can propagate into the atmosphere and, consequently accumulate into terrestrial land surface reservoirs (e.g., Bonnet et al., 2017) and vegetation (e.g., Zeng et al., 1999). This land surface memory, like in soil moisture (Alessandri and Navarra, 2008; Catalano et al., 2016) or snow (Loranty et al., 2014), may also contribute to the decadal predictability of the terrestrial component of the water cycle, but remains difficult to assess given the limitations of observational records. Vegetation initialization seems to generate as much noise as signal and does not necessarily translate into improved skill in early decadal predictions based on ESMs (Weiss et al., 2014).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Decadal hydrological predictability in an idealized setting has been also investigated through off-line land surface hindcast experiments, driven by observed atmospheric forcing and/or initial conditions, suggesting the potential for skilful predictions for terrestrial water storage, deep soil moisture, and groundwater (Yuan and Zhu, 2018). Yet, a real-world assessment is hampered by the lack of observations and is only feasible when multi-decadal records of satellite estimates of terrestrial water storage, snow mass or soil moisture are available.

In summary, there is *high confidence* that the water cycle changes that have already emerged from internal variability will become more pronounced in near-term (2021-2040) projections. However, there is *low confidence* in decadal predictions of precipitation changes, particularly over most land areas, because internal variability remains difficult to predict and can offset or amplify the forced water cycle response.

8.5.2.3 Volcanic forcing

Volcanic eruptions can affect climate projections in the near term (2021-2040) (Section 4.4.4, CCB4.1). In this chapter, they are of interest because they can trigger a transient departure from the water cycle response to anthropogenic radiative forcing. Major volcanic eruptions temporarily reduce total global and wet tropical region precipitation (*high confidence*) (Iles et al., 2014), can weaken or shift the ITCZ (Iles et al., 2014; Colose et al., 2016; Liu et al., 2016), and reduce summer monsoon rainfall (*medium confidence*) (Pausata et al., 2015b; Zambri and Robock, 2016; Zambri et al., 2017; Zuo et al., 2019; Singh et al., 2020c). Monsoon precipitation in one hemisphere can be enhanced by the remote volcanic forcing occurring in the other hemisphere (*medium confidence*) (Pausata et al., 2015a; Liu et al., 2016; Zuo et al., 2019). Over the Sahel, the sign of hydrological changes depend on the hemisphere where the volcanic eruptions occur (Haywood et al., 2013b). Out of phase changes in the Sahel and the Amazon basin are expected from the effect of volcanic aerosols on tropical Atlantic SST and the ITCZ (Hua et al., 2019). Over the last millennium, uncertainties remain in the symmetry/asymmetry of the monsoon response because it is difficult to estimate the exact latitude and season of past volcanic eruptions further back in time (Colose et al., 2016; Fasullo et al., 2019).

Data for six major eruptions over the last century along with CMIP5 historical experiments indicate that volcanic eruptions cause a detectable decrease in streamflow in northern South America, central Africa, high-latitude Asia and in wet tropical-subtropical regions, and a detectable increase in southwestern North America and southern South America (Iles and Hegerl, 2015). Attempts to include volcanic forcing in future projections show enhanced precipitation variability on annual to decadal timescales with small reductions in Asian monsoon rainfall (Bethke et al., 2017). The occurrence of volcanic eruptions in the coming century, either as single large events or clustered smaller ones, can alter the water cycle (see also CCB4.1), and regional drought events may be enhanced by co-occurring volcanic (Liu et al., 2016; Gao and Gao, 2017; Zambri et al., 2017) and GHG (e.g., Cook et al., 2018) forcing (*low confidence*). Volcanic eruptions may also lead to widespread precipitation anomalies up to several years following an eruption through their potential influence on the El Niño Southern Oscillation (*low confidence*) (Stevenson et al., 2016; Dee et al., 2020; McGregor et al., 2020).

In summary, large volcanic eruptions reduce global mean precipitation, as well as precipitation in tropical wet regions (*high confidence*). There is *low confidence* in specific regional and seasonal responses, primarily due to the limitations of the observational record.

8.5.3 Non-linearities across global warming levels

AR5 concluded that annual and seasonal mean precipitation changes can be estimated by linear pattern scaling techniques (Santer and Wigley, 1990; Arnell and Gosling, 2016; Greve et al., 2018), which represent regional changes in precipitation as a linear function of global mean temperature change. However, there are a number of caveats when pattern scaling is applied to low emission scenarios or to scenarios where localized forcing (e.g., anthropogenic aerosols) are significant and vary in time (Collins et al., 2013). Here

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the focus is in on non-linear water cycle responses to increasing global warming levels, as estimated for instance from the difference between the first 2°C of global warming, and the next 2°C of warming (Fig 8.25), and their possible underlying mechanisms.

8.5.3.1 Non-linearities in large-scale atmospheric circulation and precipitation

Since AR5, there is further evidence that the pattern scaling technique has limitations (Lopez et al., 2014; Wartenburger et al., 2017; Tachiiri et al., 2019), and that alternative approaches such as multiple regressions using the land-sea warming contrast as an additional predictor offer added value (Joshi et al., 2013). The simplest traditional pattern scaling approach approximates future changes by the product of a time-evolving global surface temperature change and a pattern that varies spatially but is constant across time, scenarios, and models. This technique was shown to be more robust across scenarios rather than across models, with better results for temperature compared with precipitation (Tebaldi and Arblaster, 2014; see also Section 4.2.4). One approach which avoids scaling is to consider a period in a different scenario with the same global surface temperature change (Herger et al., 2015). It is attractive as it provides patterns of any temporal resolution that are consistent across variables. Nonetheless, this technique is still only based on global surface temperature and is not necessarily suitable for precipitation changes projected in stabilized versus transient scenarios (at the same global warming level) given the fast-atmospheric adjustment to GHG radiative forcing (Section 8.2.1, 8.4.1.1).

Even in a theoretical climate system governed by linear processes, pattern-scaling assumptions can fail because the different forcing time response of different parts of the Earth system cause evolving spatial warming patterns (Good et al., 2016a). This occurs primarily because different feedbacks occur at different timescales (Armour et al., 2013; Andrews et al., 2015), which in turn implies that the atmospheric circulation and water cycle is dependent both on the level of warming and the rate of change (McInerney and Moyer, 2012; Ceppi et al., 2018). The usual distinction between the fast adjustment to increased GHG concentrations and the slower response to SST warming (Section 8.2.2.2) may however not be sufficient to explain the time evolution of the hydroclimatic response at the regional scale, especially in subtropical land areas where this response critically depends on shifts in atmospheric circulation associated with distinct “fast” (typically 5-10 years, that is however much slower than the atmospheric adjustment assessed in Section 8.2.1) and slow SST warming patterns (Zappa et al., 2020). The changing balance between the water cycle response to anthropogenic GHG and aerosol forcings is another source of non-linearity across time and global warming levels (Ishizaki et al., 2013; Rowell et al., 2015; Liu et al., 2019c; Wilcox et al., 2020).

Nonlinearities in the climate response are thought to arise from multiple factors. These include state-dependent ice-albedo feedback and its potential influence on Northern Hemisphere storm tracks (Peings and Magnusdottir, 2014; Semenov and Latif, 2015; see also Cross-Chapter Box 10.1 and Section 8.6.1.2); a state-dependent sensitivity of tropical precipitation to increased SST (Schewe and Levermann, 2017; He et al., 2018); a complex response of the Atlantic meridional overturning circulation (AMOC; Section 9.2.4.1 and Section 8.6.1.1) and its model- and magnitude-dependent teleconnections with regional temperature and precipitation (Kageyama et al., 2013; Jackson et al., 2015; Qasmi et al., 2017, 2020); and other atmospheric and terrestrial (Section 8.5.3.2) processes such as cloud and land surface feedbacks (Ceppi and Gregory, 2017; King, 2019). The response of convective precipitation may exhibit nonlinearities because it is itself modulated by both dynamics and atmospheric water content, each responding independently to warming (Chadwick and Good, 2013; Neupane and Cook, 2013).

Based on a simple model, it was also suggested that the Indian summer monsoon may exhibit a moisture-advection feedback which allows multiple stable states as boundary conditions change (Zickfeld et al., 2005). However, limitations of this theory and comprehensive GCMs suggest a near-linear monsoon response to a broad range of radiative forcings (Boos and Storelvmo, 2016). Non-linear precipitation responses to global warming have been reported in the Indo-Pacific, where a linear increase in SSTs can trigger nonlinear changes in precipitation and a shift in the ITCZ depending on the relative amplitudes of uniform and structured SST anomalies (Chung et al., 2014a; Toda and Watanabe, 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Compared to atmospheric circulation and seasonal mean precipitation, extreme precipitation has been found to scale more accurately with local and global mean temperature (Chou et al., 2012; Pendergrass et al., 2015). The projected increase in the magnitude of extreme precipitation is generally proportional to the global warming level, with an increase of around 7% per 1°C warming (Section 11.4.5) although this rate shows seasonal and geographical variations and is slightly less for 5-day than for 1-day precipitation maxima. Projected changes in extreme precipitation are the result of both thermodynamical and more model-dependent and potentially less linear dynamical contributions (Pfahl et al., 2017). Projected changes in precipitation extremes are also potentially sensitive to a nonlinear response of spatial convective organization (Pendergrass et al., 2016), and can exhibit a quadratic rather than linear response to global warming (Pendergrass et al., 2019).

Within CMIP6, the linearity to CO_2 forcing can be assessed through the comparison of the model response to abrupt doubling versus abrupt quadrupling of atmospheric CO_2 (Webb et al., 2017). Preliminary analyses based on CMIP5 models showed that annual precipitation changes following a doubling step change in $CO_2$from pre-industrial levels are not necessarily consistent with the response to the step from doubling to quadrupling despite a similar change in radiative forcings (Good et al., 2016a; Ceppi and Shepherd, 2017). Beyond the visual comparison of the climate response at various global warming levels (e.g., Figure 4.35), the linearity across global warming levels can be assessed by using the highest emission scenario and comparing seasonal mean relative precipitation changes at +2°C versus +4°C above preindustrial (1850-1900) temperatures (Figure 8.25). The results support the previous finding (Good et al., 2016b) that a second 2°C warming does not necessarily lead to the same precipitation anomaly pattern as the first 2°C, especially in the tropics where regional differences can be large but not necessarily consistent among different models. They are also consistent with a recent analysis of CMIP5 models showing that the projected drying in the Mediterranean and in Chile is substantially faster than the increase in GSAT, and therefore does not scale linearly with global warming (Zappa et al., 2020).

In summary, there is *high confidence* that continued global warming will further amplify GHG-induced changes in large-scale atmospheric circulation and precipitation. Nonetheless, there are cases where regional water cycle changes are not linearly related to global warming due to the interaction of multiple forcings, feedbacks and timescales (*medium confidence*, see also Section 4.2.4, Section 7.4.3, Section 8.2.1). Aridity in subtropical regions is highly sensitive to fast shifts in large-scale atmospheric circulation so are particularly susceptible to such non-linearities.

[START FIGURE 8.25 HERE]

Figure 8.25: Effect of first versus second 2°C of global warming relative to the 1850-1900 base period on seasonal mean precipitation (mm/day). CMIP6 multi-model ensemble mean DJF (left panels) and JJA (right panels) precipitation difference for a,b) SSP5-8.5 at +2°C; c,d) SSP5-8.5 at +4°C minus SSP5-8.5 at +2°C (second 2°C warming); e,f) second minus first 2°C fast warming (c-a and d-b). Only models reaching the +4°C warming levels in SSP5-8.5 are considered. Differences are computed based on 21-yr time windows centered on the first year reaching or exceeding the selected global warming level using a 21-yr running mean global surface atmospheric temperature criterion. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.25 HERE]

8.5.3.2 Non-linearities in land surface processes and feedbacks

Land surface responses and feedbacks represent a potential source of non-linearity for the water cycle response, at least at regional and local scales. The forced response of soil moisture and freshwater resources

ACCEPTED VERSION SUBJECT TO FINAL EDITING

not only depends on precipitation, but also on evaporation (Laîné et al., 2014), snowmelt (Thackeray et al., 2016), and runoff (Zhang et al., 2018e) which are intrinsically non-linear processes depending on soil moisture or temperature thresholds. Bare ground evaporation is, for instance, usually estimated as a non-linear function of surface soil moisture (Jefferson and Maxwell, 2015). Plant transpiration requires more complex formulations with non-linear dependencies on multiple environmental factors including root-zone soil moisture and atmospheric CO_2 concentration (Franks et al., 2017). Globally, land surface evaporation is both energy and soil-moisture limited, but one of these limitations can become dominant depending on regions and seasons. Non-linearities may be particularly strong in transitional regimes where and when soil moisture limitation plays a major role (Berg and Sheffield, 2018b).

Snowmelt is a non-linear process and projected changes in snowfall are also a non-linear combination of changes in total precipitation and in the fraction of solid precipitation. In cold regions, snowfall may first increase because of the increased water capacity of a warmer atmosphere and then decrease because snow falls as rain in an even warmer atmosphere. Such non-linearities can contribute to elevation, latitudinal and seasonal contrasts in the observed and projected retreat of the Northern Hemisphere snow cover (Shi and Wang, 2015; Thackeray et al., 2016). Mountain glaciers also represent source of nonlinear runoff responses since the annual runoff can first increase due to additional melting and then decrease as the glaciers shrink (Kraaijenbrink et al., 2017; Shannon et al., 2019). Section 9.5.1.3 concludes with *high confidence* that the average annual runoff from glaciers will generally reach a peak at the latest by the end of the 21st century, and decline thereafter. This peak may have already occurred for small catchments with little ice cover, but tends to occur later in basins with large glaciers. Permafrost thawing is another mechanism which can trigger a non-linear hydrological response in the high-latitudes of the Northern Hemisphere (Walvoord and Kurylyk, 2016), whose magnitude and potential abruptness is assessed in Section 5.4.3.3.

Land surface runoff and groundwater recharge are highly nonlinear process, depending for instance on rainfall intensity, soil infiltration capacity, vertical profile of soil moisture and water table depth. A non-linear relationship between rainfall and groundwater recharge was observed in the tropics where intense seasonal rainfalls associated with internal climate variability contribute disproportionately to recharge (Taylor et al., 2013b; Cuthbert et al., 2019a). Groundwater fluxes in arid regions are generally less responsive to climate variability than in humid regions, which can temporarily buffer climate change impacts on water resources or lead to a long, initially hidden, hydrological responses to global warming (Cuthbert et al., 2019a). Hydrological model simulations driven by individual and combined forcing show that decreased precipitation can cause larger deficits in soil moisture, streamflow and water table depth than other forcings, but also that these factors are not linearly cumulative when applied in combination (Hein et al., 2018). Surface runoff was found to scale only approximately with global warming (Tanaka and Takahashi, 2017). Significant non-linearities were found in the projected annual mean runoff response to global warming in CMIP5 projections, which could not be entirely explained by precipitation changes (Zhang et al., 2018). Similar nonlinear behaviours are found in CMIP6 models over the Amazon, Yangtze, Niger, Euphrates and Mississippi river basins (Figure 8.26), highlighting the need to reassess the assumption of linearity when estimating regional water cycle changes.

Beyond changes in land surface water fluxes, nonlinearities in the response of soil moisture and freshwater reservoirs have not been well documented in global climate projections but deserve further attention given the complex interactions between the water, energy and carbon cycles (Berg and Sheffield, 2018a), the growing direct human influence on rivers and groundwater (Abbott et al., 2019), and a possible offset between the linear components of changes in precipitation and evapotranspiration. Significant nonlinearities were found in water scarcity projections, as seen by the stronger sensitivity to the first 2°C increase in global warming (Gosling and Arnell, 2016).

In summary, there is both numerical and process-based evidence that terrestrial water cycle changes can be nonlinear at the regional scale (*high confidence*). Nonlinear regional responses of runoff, groundwater recharge and water scarcity have been documented based on both CMIP5 and CMIP6 models, and highlight the limitations of simple pattern-scaling techniques (*medium confidence*). Water resources fed by melting glaciers are particularly exposed to such nonlinearities (*high confidence*).

[START FIGURE 8.26 HERE]

Figure 8.26: Rate of change in basin-scale annual mean runoff with increasing global warming levels. Relative changes (%) in basin-averaged annual mean runoff estimated as multi-model ensemble median from a variable subset of CMIP6 models for each SSP over six major river basins: a) Mississipi, b) Danube, c) Lena, d) Amazon, e) Euphrates, f) Yangtze, g) Niger, h) Indus, i) Murray. The basin averages have been estimated after a first-order conservative remapping of the model outputs on the 0.5° by 0.5° river network of (Decharme et al., 2019). The shaded area indicates the 5-95% confidence interval of the ensemble values across all SSPs. Note that the y-axis range differs across basins and is particularly large for Niger and Murray (panels g and i). The number of models considered is specified for each scenario in the legend located inside panel b. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.26 HERE]

8.6 What is the potential for abrupt change?

In this report, *abrupt change* is defined as a regional-to-global scale change in the climate system that occurs faster than the typical rate of changes in its history, implying non-linearity in the climate response (see Annex VII: Glossary). Often, abrupt change arises from positive feedbacks in the climate system that cause the current state to become unstable, and cross a 'tipping point' (Lenton et al., 2008); i.e., a rapid shift from one climate state to another. The water cycle has several attributes with potential to produce abrupt change. Non-linear interactions between the ocean, atmosphere, and land surface can result in rapid shifts between wet and dry states (Sections 8.6.1 and 8.6.2). Cessation of solar radiation modification could also result in abrupt changes in the water cycle (Section 8.6.3). This section reviews these types of abrupt shifts and assesses the likelihood that they will occur by 2100.

8.6.1 Abrupt water cycle responses to a collapse of Atlantic Meridional Overturning Circulation

Multiple lines of evidence, including both paleoclimate reconstructions and simulations, suggest that a severe weakening or collapse of Atlantic Meridional Overturning Circulation (AMOC, see Glossary) causes abrupt and profound changes in the global hydrological cycle (Chiang and Bitz, 2005; Broccoli et al., 2006; Chiang and Friedman, 2012; Jackson et al., 2015; Renssen et al., 2018). Deep water formation in the North Atlantic is dependent on a delicate balance of heat and salt fluxes (Buckley and Marshall, 2016); disruption in either of these due to melting ice sheets, a change in precipitation and evaporation, or ocean circulation can force AMOC to cross a tipping point (Drijfhout et al., 2015) (SROCC). During the last deglacial transition, one such slowdown in AMOC—during the Younger Dryas event (12,800–11,700 years ago)—caused worldwide changes in precipitation patterns. These included a southward migration of the tropical ITCZ (Peterson et al., 2000; McGee et al., 2014; Schneider et al., 2014; Mohtadi et al., 2016; Reimi and Marcantonio, 2016; Wang et al., 2017c) and systematic weakening of the African and Asian monsoons (Tierney and deMenocal, 2013; Otto-Bliesner et al., 2014; Cheng et al., 2016; Grandey et al., 2016; Wurtzel et al., 2018). Conversely, the Southern Hemisphere monsoon systems intensified (Cruz et al., 2005; Ayliffe et al., 2013; Strikis et al., 2015, 2018a; Campos et al., 2019). Drying occurred in Mesoamerica (Lachniet et al., 2013) while the North American monsoon system was largely unaffected (Bhattacharya et al., 2018). The mid-latitude region in North America was wetter (Polyak et al., 2004; Grimm et al., 2006; Wagner et al., 2010; Voelker et al., 2015), while Europe was drier (Genty et al., 2006; Rach et al., 2017; Naughton et al., 2019). A transient coupled climate model simulation was able to reproduce the large-scale precipitation response to such an event (Liu et al., 2009) (Figure 8.27a).

These patterns of past hydroclimatic change are relevant for future projections because it is *very likely* that AMOC will weaken by 2100 in response to increased greenhouse gas emissions (Weaver et al., 2012; Drijfhout et al., 2015; Bakker et al., 2016; Reintges et al., 2017) (See also Section 9.2.3.1). Furthermore, there is *medium confidence* that the decline in AMOC will not involve an abrupt collapse before 2100

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Section 9.2.3.1). The response of precipitation to hypothetical AMOC collapse under elevated greenhouse gases bears resemblance to the paleoclimate response during the Younger Dryas event, with some important differences due to effects of increased CO_2 on global precipitation patterns (Figure 8.27b). As with the paleoclimate events, AMOC collapse results in a southward shift in the ITCZ that is most pronounced in the tropical Atlantic. This could cause drying in the Sahel region (Defrance et al., 2017) as well as Mesoamerica and northern Amazonia (Parsons et al., 2014; Chen et al., 2018c). AMOC collapse also causes the Asian monsoon systems to weaken (Liu et al., 2017b) (Figure 8.27b) counteracting the strengthening expected in response to elevated greenhouse gases (see Section 8.4.2). Europe is projected to experience moderate drying in response to AMOC collapse (Jackson et al., 2015).

[START FIGURE 8.27 HERE]

Figure 8.27: (a) Model simulation of precipitation response to the Younger Dryas event relative to the preceding warm Bølling-Allerød period (base colours, calculated as the difference between 12,600–11,700 yr BP and 14,500–12,900 BP from the TraCE paleoclimate simulation of Liu et al., (2009)), with paleoclimate proxy evidence superimposed on top (dots). (b) Model simulation of precipitation response to an abrupt collapse in AMOC under a doubling of 1990 CO_2 levels (after Liu et al., (2017)). Regions with rainfall rates below 20 mm/year are masked. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

[END FIGURE 8.27 HERE]

In summary, given that there is *medium confidence* that the decline in AMOC will not involve an abrupt collapse before 2100, there is *low confidence* that an AMOC-driven abrupt change in the water cycle will occur by 2100. However, if AMOC collapse does occur, it is *very likely* that there would be large regional impacts on the water cycle.

8.6.2 Abrupt water cycle responses to changes in the land surface

Changes in the land surface, including vegetation cover and dust emissions, can trigger abrupt changes in the water cycle. Plants regulate the exchange of water and energy between the land surface and the atmosphere (Section 8.2.3.3), such that sudden shifts in plant functions, types, or biomes can trigger feedbacks that have the potential to cause abrupt changes in the regional water cycle. Dust emissions, from either climatic or land use changes, affect the radiation budget and can regionally exacerbate dry extremes. Below, we assess the likelihood of abrupt changes in the water cycle for the well-studied regions of the Amazon and the Sahel, and the potential for dust emissions to amplify drought and aridity.

8.6.2.1 Amazon deforestation and drying

The Amazon forest plays an active role in driving atmospheric moisture transport and generating precipitation in the South American region (Drumond et al., 2014; Poveda et al., 2014; Yin et al., 2014; Staal et al., 2018, 2020; Agudelo et al., 2019; Espinoza et al., 2019) (SRCCL). This close association between the land surface and the water cycle makes the Amazon a potential hotspot for abrupt change (Torres and Marengo, 2014). Both deforestation and drying are projected to increase by 2100, resulting in a worst-case scenario of up to a 50% loss in forest cover by 2050 (Soares-Filho et al., 2006; Boisier et al., 2015; Steege et al., 2015; Gomes et al., 2019). Deforestation in the Amazon also raises the probability of catastrophic fires (Brando et al., 2014). The combination of deforestation, drier conditions, and increased fire can push the rainforest ecosystem past a tipping point, beyond which there is rapid land surface degradation, a sharp reduction in atmospheric moisture recycling, an increase in the fraction of precipitation that runs off, and a further shift towards a drier climate (Staal et al., 2015; Boers et al., 2017; Zemp et al., 2017; Ruiz-Vásquez et al., 2020). A rapid drop in precipitation has a direct impact on river flows, driving basin-scale shifts from a regulated to unregulated state (Salazar et al., 2018). Regional climate modeling experiments confirm that

ACCEPTED VERSION SUBJECT TO FINAL EDITING

increased deforestation leads to a drier climate, although not all models show a true tipping point, at least under present-day climatic conditions (Lejeune et al., 2015; Spracklen and Garcia-Carreras, 2015).

In AR5, some simulations using a coupled climate-carbon cycle model exhibited an abrupt dieback of the Amazon forest in future climate scenarios (Oyama and Nobre, 2003; Cox et al., 2004; Malhi et al., 2008). However, subsequent work demonstrated that abrupt Amazon dieback does not occur consistently across, or even within, Earth system models (Lambert et al., 2013; Boulton et al., 2017). The occurrence of dieback is highly dependent on both how dry the simulated climate is in the present day (Malhi et al., 2009) as well as the representation of forest structure and competitive dynamics (Levine et al., 2016). Models with a low diversity of plant characteristics and types have a higher tendency for abrupt change (Sakschewski et al., 2016). Abrupt shifts and ecosystem disruptions can occur on the sub-regional level (Pires and Costa, 2013), highlighting the need for higher-resolution modelling studies. Since AR5, CMIP6 projections suggest that a tipping point in the Amazon system may be crossed on a local or regional scale (Staal et al., 2020) but continue to be highly dependent on model biases in precipitation and the simulation of the land surface. Consequently, the timing, and probability, of an abrupt shift remains difficult to ascertain.

In summary, while there is a strong theoretical expectation that Amazon drying and deforestation can cause a rapid change in the regional water cycle, currently there is *limited* model *evidence* to verify this response, hence there is *low confidence* that such a change will occur by 2100.

8.6.2.2 Greening of the Sahara and the Sahel

Greening of the Sahara and Sahel regions in North Africa, in response to an increase in precipitation, has long been considered an amplifying mechanism that can lead to abrupt change. Although the high surface albedo of the desert stabilizes the energy balance of the system (Charney, 1975), greening can induce strong, positive feedbacks between the land surface and precipitation that can shift the region into a "Green Sahara" state. The fact that the transition phase between a Desert Sahara and Green Sahara is not theoretically stable (Brovkin et al., 1998) creates a tipping point and allows for the possibility of an abrupt shift between dry and wet climate regimes. Paleoclimate reconstructions provide evidence of past "Green Sahara" states (deMenocal and Tierney, 2012), under which rainfall rates increased by an order of magnitude (Tierney et al., 2017), leading to a vegetated landscape (Jolly et al., 1998) with large lake basins (Gasse, 2000; Drake and Bristow, 2006). The underlying driver of the Green Sahara is the periodic increase in summer insolation associated with the orbital precession cycle (Kutzbach, 1981). In this sense, Green Saharas are not direct analogues for a response to anthropogenic greenhouse gas emissions, as these past states were forced by natural, seasonal changes in solar radiation. However, the climate dynamics of Green Saharas (which have global impacts, Pausata et al., (2020)), and the speed of the transitions between Desert Saharas and Green Saharas, are relevant for future projections.

Since AR5, paleoclimatic studies have improved our view of the timing, spatial extent, and speed of transitions associated with the early Holocene (11,000–5,000 yr BP) Green Sahara. Observed transitions into and out of Green Sahara states are always faster than the underlying forcing, in agreement with theoretical considerations (*high confidence*) (Tierney and deMenocal, 2013; Shanahan et al., 2015; Tierney et al., 2017). However, there is *low confidence* in the duration of the transition because sedimentary records cannot typically resolve changes on decadal—multi-decadal timescales (Tierney and deMenocal, 2013). Both paleoclimate data and modelling experiments suggest that the timing and speed of the transition was spatially heterogeneous (*high confidence*), with northern Saharan locations becoming drier thousands of years before more equatorial locations (Shanahan et al., 2015; Tierney et al., 2017; Dallmeyer et al., 2020). These observations are consistent with theoretical studies suggesting that spatial heterogeneity and diversity in ecosystems can mitigate the probability of catastrophic change (Van Nes and Scheffer, 2005; Bathiany et al., 2013). Conversely, low ecosystem diversity can produce local or regional "hot spots" of abrupt change such as those seen in some paleoclimate records (Claussen et al., 2013).

CMIP5 and CMIP6 models**,** some of which include dynamic vegetation schemes, cannot simulate the magnitude, nor the spatial extent, of greening and precipitation change associated with the last Green Sahara

ACCEPTED VERSION SUBJECT TO FINAL EDITING

under standard mid-Holocene (6 ka) boundary conditions (*high confidence*) (Harrison et al., 2014; Tierney et al., 2017; Brierley et al., 2020) (Figure 3.11). This result remains unchanged since AR4 (Jansen et al., 2007). This may be due to climatological biases in the models (Harrison et al., 2015) or could imply that the strength of the feedbacks between vegetation and the water cycle in the models is too weak (Hopcroft et al., 2017). To date, climate models still only produce the amount and spatial extent of rainfall that is needed to sustain a Green Sahara if they are given prescribed changes in the land surface, such as albedo, soil moisture, vegetation cover and/or dust emissions (Pausata et al., 2016; Skinner and Poulsen, 2016; Tierney et al., 2017).

Some climate model simulations suggest that under future high-emissions scenarios, CO_2 radiative forcing causes rapid greening in the Sahel and Sahara regions via precipitation change (Claussen et al., 2003; Drijfhout et al., 2015). For example, in the BNU-ESM RCP8.5 simulation, the change is abrupt with the percentage of bare soil dropping from 45% to 15%, and percentage of tree cover rising from 50% to 75%, within 10 years (2050-2060) (Drijfhout et al., 2015). However, other modelling results suggest that this may be a short-lived response to CO_2 fertilization (Bathiany et al., 2014).

In summary, given outstanding uncertainties in how well the current generation of climate models capture land-surface feedbacks in the Sahel and Sahara, there is *low confidence* that an abrupt change to a greener state will occur in these regions before 2100 or 2300.

8.6.2.3 Amplification of drought by dust

Mineral dust aerosols in the climate system originate from both semi-permanent and transient sources (Prospero et al., 2002; Ginoux et al., 2012). The former are typically arid regions where significant alluvial sediments have accumulated over time, while the latter are often associated with natural (e.g., droughts, wildfires) and anthropogenic (e.g. land use change, desertification) disturbances. Modern-day dust emissions are dominated by natural sources (Ginoux et al., 2012), although human emissions may contribute 10–60% of the global atmospheric dust load (Webb and Pierre, 2018). Paleo-dust records suggest that human factors (land use change and landscape disturbance) may have doubled global dust emissions between1750 and the last quarter of the 20th century (Hooper and Marx, 2018) (Section 2.2.6).

Dust aerosols influence the climate system and hydrologic cycle through both direct impacts on radiation (absorbing and scattering longwave and shortwave) and via indirect effects on cloud and precipitation processes (Choobari et al., 2014; Kok et al., 2018; Schepanski, 2018) (Box 8.1). The capacity of dust aerosols to suppress precipitation by reducing humidity and energy availability, and increasing stability in the atmosphere (Cook et al., 2013; Huang et al., 2014) can drive positive feedbacks (see also Section 6.3.6). Thus there is strong potential for dust to contribute to abrupt changes in the water cycle, especially in semi-arid regions where wind erosion is highly sensitive to vegetation cover and drought variability (Yu et al., 2015). One such event occurred over the Central United States during the 1930s: the Dust Bowl drought, an iconic event characterized by widespread land degradation and historically unprecedented levels of dust storm activity (Hansen and Libecap, 2004; Lee and Gill, 2015). While initialized by warm sea-surface temperatures in the North Atlantic, modeling work indicates that land cover changes and resulting dust emissions contributed to the severity and spatial extent of the drought by further suppressing precipitation (Cook et al., 2009; Hu et al., 2018; Cowan et al., 2020). There is also increasing evidence that dust aerosol feedbacks are necessary to explain the magnitude of rainfall increase during the mid-Holocene Green Sahara (Pausata et al., 2016; Tierney et al., 2017).

The importance of dust aerosol feedbacks in future abrupt climate events, like droughts or rapid aridification, is unclear. In part, this is because the response of dust aerosol emissions and loading levels in the atmosphere to climate change is highly uncertain (Tegen and Schepanski, 2018; Webb and Pierre, 2018). This difficulty in predicting future dust responses is rooted in the fact that emissions depend on both changes to the land surface (e.g., land use/land cover change, aridification, ecological responses to climate change) and the state of the atmosphere (Tegen and Schepanski, 2018). While there is some evidence that global dust aerosol concentrations in the future will increase (Allen et al., 2016; Tegen and Schepanski, 2018), it is highly

ACCEPTED VERSION SUBJECT TO FINAL EDITING

dependent on changes in precipitation patterns and atmospheric circulation (see the SRCCL, Section 2.4.1), and it is not clear what the radiative impact will be (Allen et al., 2016; Kok et al., 2018).

In summary, due to *limited evidence*, there is *low confidence* regarding the role of dust in abrupt climate change events over the next century.

8.6.3 Abrupt water cycle responses to initiation or termination of solar radiation modification

Solar radiation modification (SRM) techniques seek to reduce the impacts of climate change by modifying the Earth's radiation budget, either by reflecting incoming solar radiation or increasing the amount of heat lost to space. Note that, following SR1.5, the definition of SRM in this report refers to changes in both solar and longwave radiation (Section 4.6.3.3 and Annex VII: Glossary). A variety of methods have been proposed, including injection of aerosols or their precursors into the stratosphere, cloud brightening, and cirrus cloud thinning (Table 4.8). Since SRM alters the planetary energy balance, changes in the hydrological cycle are theoretically expected (Section 8.2). These changes can be abrupt if the initial magnitude of SRM is large, rather than increased gradually. Since AR5, a diversity of SRM techniques have been tested using climate model simulations, with an increasing focus on consequences for regional water availability. Techniques targeting shortwave radiation (sulfate injection, surface albedo modification, cloud brightening) are *likely* to reduce global mean precipitation relative to future CO_2 emissions scenarios (Bala et al., 2008; Jones et al., 2013a; Tilmes et al., 2013; Ferraro et al., 2014; Crook et al., 2015). In contrast, cirrus cloud thinning, a longwave technique, results in increased global precipitation as it causes enhanced radiative cooling in the troposphere (*medium confidence*) (Crook et al., 2015; Kristjánsson et al., 2015; Jackson et al., 2016).

The magnitude of hydrological disruption for both the initiation and termination of SRM depends on the method used, as well as the strength and duration of its implementation (Ekholm and Korhonen, 2016; Irvine et al., 2019). Under abrupt SRM implementation, hydrological shifts are rapid, occurring within the first decade (Crook et al., 2015). Artificial enhancement of albedo in Northern Hemisphere desert regions causes a southward shift in the Hadley Cell and ITCZ, and extreme drying in the northern tropics (Crook et al., 2015). Uniform or tropical stratospheric sulfate injection weakens the African and Asian summer monsoons and causes drying in the Amazon (Robock et al., 2008; Crook et al., 2015; Dagon and Schrag, 2016). Changes in evapotranspiration can produce large deficits or surpluses in soil moisture and runoff in different regions and seasons (Dagon and Schrag, 2016).

Rapid changes (years to decades) in the hydrological cycle are also expected if SRM is terminated abruptly, either purposefully or because of technical failure or political disagreement. We reiterate the AR5 conclusion that, if SRM "were terminated for any reason, there is *high confidence* that surface temperatures would increase rapidly (within a decade or two) to values consistent with the GHG forcing." The additional global warming caused by SRM termination may result in a rapid increase in global mean precipitation (*medium confidence*) (Jones et al., 2013). Heterogenous regional and seasonal changes are also expected, but are model-dependent (Jones et al., 2013a). As with SRM initiation, the impact of SRM termination is expected to be dependent on the technique deployed.

In summary, it is *very likely* that abrupt water cycle changes will occur if SRM is abruptly initiated or halted, especially in tropical regions. Further assessment of the potential side-effects of SRM is found in Section 4.6.3.3.

8.7 Final remarks

Despite the advances presented in this chapter, there are still many opportunities to improve the understanding and quantification of human influences on past, present and future water cycle changes:

- Extension and development of pre-instrumental data and paleoclimate records, particularly from the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Southern Hemisphere, will improve estimates of the range of natural climate variability and extremes, and our knowledge of how the water cycle responded in past high CO_2 climates.

- Development of longer observational time series that will improve our understanding of physical processes and the analysis and simulation of natural modes of weather and climate variability.

- The use of large model ensembles will help better understand the interactions between climate change and internal variability and in the detection and attribution of observed water cycle changes.

- The simulation of precipitation, latent heating and radiative effects of deep convective clouds would greatly benefit from a better representation of their interactions with aerosols.

- An improvement of the GCM-simulated precipitation, latent heating and radiative effects of deep convective clouds would benefit from an improved representation of their interactions with aerosols.

- Further research on land surface processes, including groundwater recharge, the role of plant physiological changes, land use change, dams and irrigation, will improve future projections of key aspects of the terrestrial water cycle such as aridity and drought.

- Ongoing efforts to develop higher-resolution, 'convection permitting', regional or global climate models will lead to an improved simulation of clouds and precipitation, their coupling with boundary layer and surface processes, their diurnal cycle and high-frequency variability, and their response to climate change, including extreme precipitation events.

- Further analysis of past and current climate variability alongside future climate change projections will provide physically understood constraints for improving the accuracy of regional water cycle simulations, adding value to the results obtained from global climate models.

- Increased understanding of internal variability and interactions with human-induced change will improve efforts to attribute changes in the water cycle and to understand and anticipate future non-linear change.

Frequently Asked Questions

FAQ 8.1: How does land use change alter the water cycle?

The ways in which humans use and change land cover, for example, by converting fields to urban areas or clearing forests, can affect every aspect of the water cycle. Land-use changes can alter precipitation patterns and how water is absorbed into the ground, flows into streams and rivers, or floods the land surface, as well as how moisture evaporates back into the air. Changes in any of these aspects of the interconnected water cycle can affect the entire cycle and the availability of freshwater resources.

Land use describes the combination of activities and ground cover defining each area of the Earth's continental surface. Altering land use can modify the exchange of water between the atmosphere, soil and sub-surface (FAQ 8.1, Figure 1).

For instance, changes in land cover can affect the ability of soils to soak up surface water (infiltration). When soil loses its capacity to soak up water, precipitation that would normally infiltrate and contribute to groundwater reserves will instead overflow, increasing surface water (runoff) and the likelihood of flooding. For example, changing from vegetation to urban cover can cause water to flow rapidly over buildings, roads and driveways and into drains rather than soaking into the ground. Deforestation over wide areas can also directly reduce soil moisture, evaporation and rainfall locally but can also cause regional temperature changes that affect rainfall patterns.

Extracting water from the ground and river systems for agriculture, industry and drinking water depletes ground water and can increase surface evaporation because water that was previously in the ground is now in direct contact with the atmosphere, being available for evaporation

Changing land use can also alter how wet the soil is, influencing how quickly the ground heats up and cools down and the local water cycle. Drier soils evaporate less water into the air but heat up more in the day. This can lead to warmer, more buoyant plumes of air that can promote cloud development and precipitation if there is enough moisture in the air.

Changes in land use can also modify the amount of tiny aerosol particles in the air. For instance, industrial and domestic activities can contribute to aerosol emissions, as do natural environments such as forests or salt lakes. Aerosols cool down global temperature by blocking out sunlight but can also affect the formation of clouds and therefore the occurrence of precipitation (see FAQ 7.2).

Vegetation plays an important role in soaking up soil moisture and evaporating water into the air (*transpiration*) through tiny holes (*stomata*) that allow the plants to take in carbon dioxide. Some plants are better at retaining water than others, so changes in vegetation can affect how much water infiltrates into the ground, flows into streams and rivers, or is evaporated.

More globally, land-use change is currently responsible for about 15% of the emissions of carbon dioxide from human activities, leading to global warming, which in turn affects precipitation, evaporation, and plant transpiration. In addition, higher atmospheric concentrations of carbon dioxide due to human activities can make plants more efficient at retaining water because the stomata do not need to open so widely. Improved land and water management (e.g., reforestation, sustainable irrigation) can also contribute to reducing climate change and adapting to some of its adverse consequences.

In summary, there is abundant evidence that changes in land use and land cover alter the water cycle globally, regionally and locally, by changing precipitation, evaporation, flooding, ground water, and the availability of fresh water for a variety of uses. Since all the components of the water cycle are connected (and linked to the carbon cycle), changes in land use trickle down to many other components of the water cycle and climate system.

FAQ 8.2: Will floods become more severe or more frequent as a result of climate change?

A warmer climate increases the amount and intensity of rainfall during wet events, and this is expected to amplify the severity of flooding. However, the link between rainfall and flooding is complex, so while the most severe flooding events are expected to worsen, floods could become rarer in some regions.

Floods are a natural and important part of the water cycle but they can also threaten lives and safety, disrupt human activities, and damage infrastructure. Most inland floods occur when rivers overtop their banks (*fluvial* flooding) or when intense rainfall causes water to build up and overflow locally (*pluvial* flooding). Flooding is also caused by coastal inundation by the sea, rapid seasonal melting of snow, and the accumulation of debris, such as vegetation or ice, that stops water from draining away.

Climate change is already altering the location, frequency and severity of flooding. Close to the coasts, rising sea levels increasingly cause more frequent and severe coastal flooding, and the severity of these floods is exacerbated when combined with heavy rainfall. The heavy and sustained rainfall events responsible for most inland flooding are becoming more intense in many areas as the climate warms because air near Earth's surface can carry around 7% more water in its gas phase (vapour) for each 1°C of warming. This extra moisture is drawn into weather systems, fueling heavier rainfall (FAQ 8.2, Figure 1).

A warming climate also affects wind patterns, how storms form and evolve, and the pathway those storms usually travel. Warming also increases condensation rates, which in turn releases extra heat that can energize storm systems and further intensify rainfall. On the other hand, this energy release can also inhibit the uplift required for cloud development, while increases in particle pollution can delay rainfall but invigorate storms. These changes mean that the character of precipitation events (how often, how long-lasting and how heavy they are) will continue to change as the climate warms.

In addition to climate change, the location, frequency and timing of the heaviest rainfall events and worst flooding depend on natural fluctuations in wind patterns that make some regions unusually wet or dry for months, years, or even decades. These natural variations make it difficult to determine whether heavy rainfall events are changing locally as a result of global warming. However, when natural weather patterns bring heavy and prolonged rainfall in a warmer climate, the intensity is increased by the larger amount of moiture in the air.

An increased intensity and frequency of record-breaking daily rainfall has been detected for much of the land surface where good observational records exist, and this can only be explained by human-caused increases in atmospheric greenhouse gas concentrations. Heavy rainfall is also projected to become more intense in the future for most places. So, where unusually wet weather events or seasons occur, the rainfall amounts are expected to be greater in the future, contributing to more severe flooding.

However, heavier rainfall does not always lead to greater flooding. This is because flooding also depends upon the type of river basin, the surface landscape, the extent and duration of the rainfall, and how wet the ground is before the rainfall event (FAQ 8.2, Figure 1) Some regions will experience a drying in the soil as the climate warms, particularly in sub-tropical climates, which could make floods from a rainfall event less probable because the ground can potentially soak up more of the rain. On the other hand, less frequent but more intense downpours can lead to dry, hard ground that is less able to soak up heavy rainfall when it does occur, resulting in more runoff into lakes, rivers and hollows. Earlier spring snowmelt combined with more precipitation falling as rain rather than snow can trigger flood events in cold regions. Reduced winter snow cover can, in contrast, decrease the chance of flooding arising from the combination of rainfall and rapid snowmelt. Rapid melting of glaciers and snow in a warming climate is already increasing river flow in some regions, but as the volumes of ice diminish, flows will peak and then decline in the future. Flooding is also affected by changes in the management of the land and river systems. For example, clearing forests for agriculture or building cities can make rain water flow more rapidly into rivers or low lying areas. On the other hand, increased extraction of water from rivers can reduce water levels and the likelihood of flooding.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

A mix of both increases and decreases in flooding have been observed in some regions and these changes have been attributed to multiple causes, including changes in snowmelt, soil moisture and rainfall. Although we know that a warming climate will intensify rainfall events, local and regional trends are expected to vary in both direction and magnitude as global warming results in multiple, and sometimes counteracting, influences. However, even accounting for the many factors that generate flooding, when weather patterns cause flood events in a warmer future, these floods will be more severe.

FAQ 8.3: What causes droughts, and will climate change make them worse?

Droughts usually begin as a deficit of precipitation, but then propagate to other parts of the water cycle (soils, rivers, snow/ice and water reservoirs). They are also influenced by factors like temperature, vegetation and human land and water management. In a warmer world, evaporation increases, which can make even wet regions more susceptible to drought.

A drought is broadly defined as drier than normal conditions; that is, a moisture deficit relative to the average water availability at a given location and season. Since they are locally defined, a drought in a wet place will not have the same amount of water deficit as a drought in a dry region. Droughts are divided into different categories based on where in the water cycle the moisture deficit occurs: meteorological drought (precipitation), hydrological drought (runoff, streamflow, and reservoir storage), and agricultural or ecological drought (plant stress from a combination of evaporation and low soil moisture). Special categories of drought also exist. For example, a snow drought occurs when winter snowpack levels are below average, which can cause abnormally low streamflow in subsequent seasons. And while many drought events develop slowly over months or years, some events, called flash droughts, can intensify over the course of days or weeks. One such event occurred in 2012 in the midwestern region of North America and had a severe impact on agricultural production, with losses exceeding $30 billion US dollars. Droughts typically only become a concern when they adversely affect people (reducing water available for municipal, industrial, agricultural, or navigational needs) and/or ecosystems (adverse effects on natural flora and fauna). When a drought lasts for a very long time (more than two decades) it is sometimes called a megadrought.

Most droughts begin when precipitation is below normal for an extended period of time (meteorological drought). This typically occurs when high pressure in the atmosphere sets up over a region, reducing cloud formation and precipitation over that area and deflecting away storms. The lack of rainfall then propagates across the water cycle to create agricultural drought in soils and hydrological drought in waterways. Other processes act to amplify or alleviate droughts. For example, if temperatures are abnormally high, evaporation increases, drying out soils and streams and stressing plants beyond what would have occurred from the lack of precipitation alone. Vegetation can play a critical role because it modulates many important hydrologic processes (soil water, evapotranspiration, runoff). Human activities can also determine how severe a drought is. For example, irrigating croplands can reduce the socioeconomic impact of a drought; at the same time, depletion of groundwater in aquifers can make a drought worse.

The effect of climate change on drought varies across regions. In the subtropical regions like the Mediterranean, southern Africa, southwestern Australia and southwestern South America, as well as tropical central America, western Africa and the Amazon basin, precipitation is expected to decline as the world warms, increasing the possibility that drought will occur throughout the year (FAQ 8.3, Figure 1). Warming will decrease snowpack, amplifying drought in regions where snowmelt is an important water resource (such as in southwestern South America). Higher temperatures lead to increased evaporation, resulting in soil drying, increased plant stress, and impacts on agriculture, even in regions where large changes in precipitation are not expected (such as central and northern Europe). If emissions of greenhouse gases are not curtailed, about a third of global land areas are projected to suffer from at least moderate drought by 2100. On the other hand, some areas and seasons (such as high-latitude regions in North America and Asia, and the South Asian monsoon region) may experience increases in precipitation as a result of climate change, which will decrease the likelihood of droughts. FAQ 8.3, Figure 1 highlights the regions where climate change is expected to increase the severity of droughts.

[START FAQ 8.3, FIGURE HERE]

FAQ 8.3, Figure 1: Drought is expected to get worse in the regions highlighted in brown as a consequence of climate change. This pattern is similar regardless of the emissions scenario; however, the magnitude of change increases under higher emissions.

Acknowledgements

The authors are extremely grateful to the WGI Bureau and Technical Support Unit for their outstanding support throughout the writing of the chapter. Special thanks to Sarah Connors for her exceptional contribution to the development of this chapter. Her help with chapter meetings and organisational support was invaluable. Thanks to Sophie Berger, Melissa Gomis, Nigel Hawtin and Tom Maycock for their contributions to figures and tables. We must also make a special acknowledgment of our chapter scientists, Sabin Thazhe Purayil and Stéphane Sénési, without whom we could not have completed our assessment nor could we have produced the excellent figures that appear in the chapter. We would also like to thank all reviewers for their useful comments. Finally, we are infinitely indebted to our families for their extended patience and support during this demanding process.

Figures

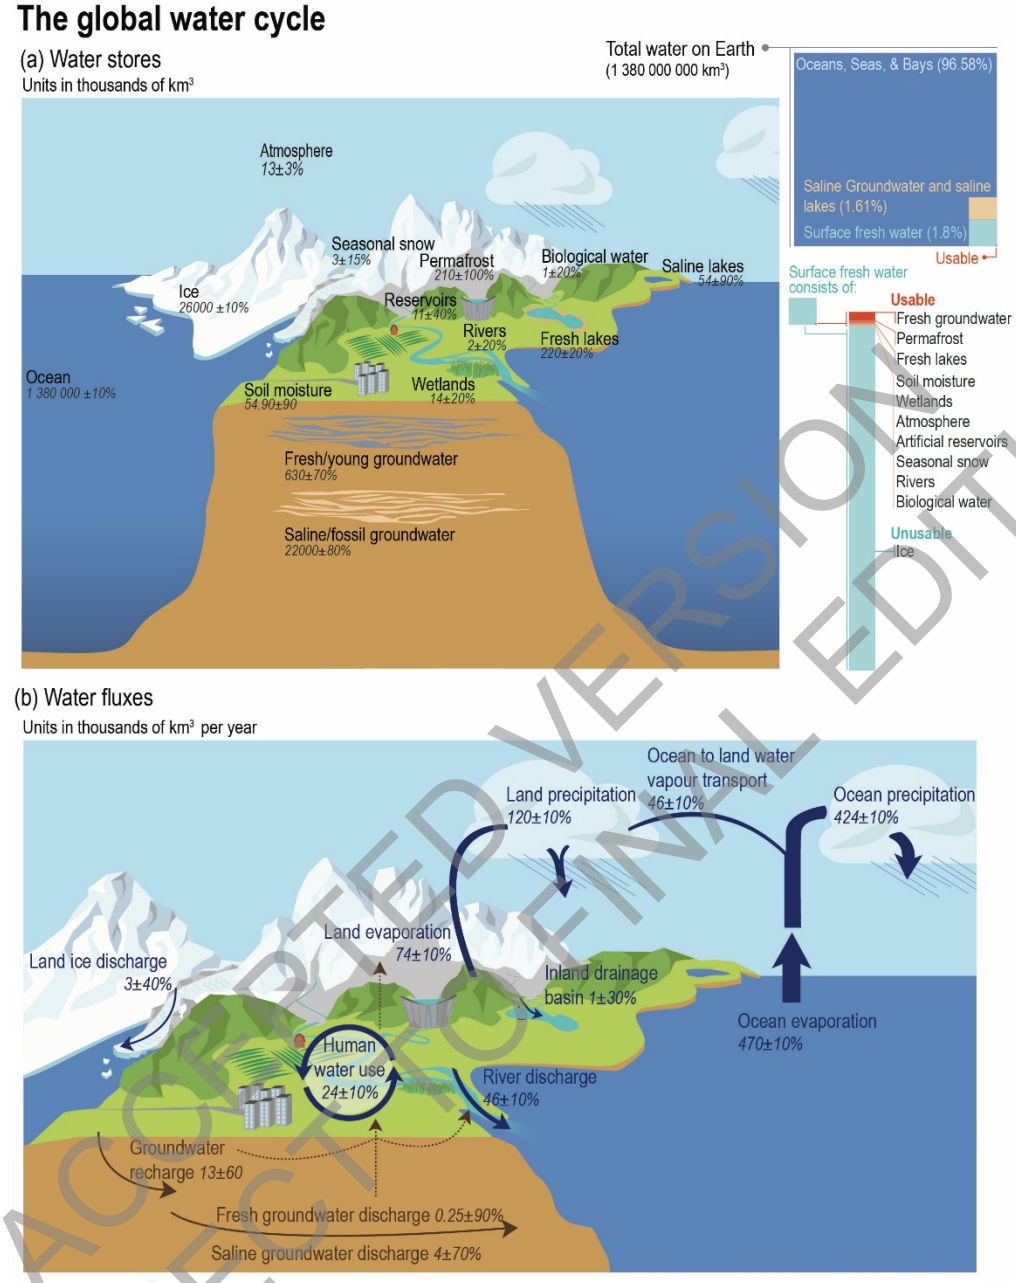

Figure 8.1: Depiction of the water cycle based on previous assessments (Trenberth et al., 2011; Rodell et al., 2015; Abbott et al., 2019) with minor adjustments for groundwater flows (Kwon et al., 2014; Zhou et al., 2019; Luijendijk et al., 2020), seasonal snow (Pulliainen et al., 2020) and ocean precipitation and evaporation (Stephens et al., 2012; Allan et al., 2020; Gutenstein et al., 2020). In the atmosphere, which accounts for only 0.001% of all water on Earth, water primarily occurs as a gas (water vapour), but it is also present as ice and liquid water within clouds. The ocean is the primary water reservoir on Earth, which is comprised mostly of liquid water across much of the globe, but also includes areas covered by ice in polar regions. Liquid freshwater on land forms surface water (lakes, rivers), soil moisture and groundwater stores, together accounting for 1.8% of global water (Stocker et al., 2013). Solid terrestrial water that occurs as ice sheets, glaciers, snow and ice on the surface and permafrost currently represents 2.2% of the planet's water (Stocker et al., 2013). Water that falls as snow in winter provides soil moisture and streamflow after melting, which are essential for human activities and ecosystem functioning.

SUBJECT TO FINAL EDITING

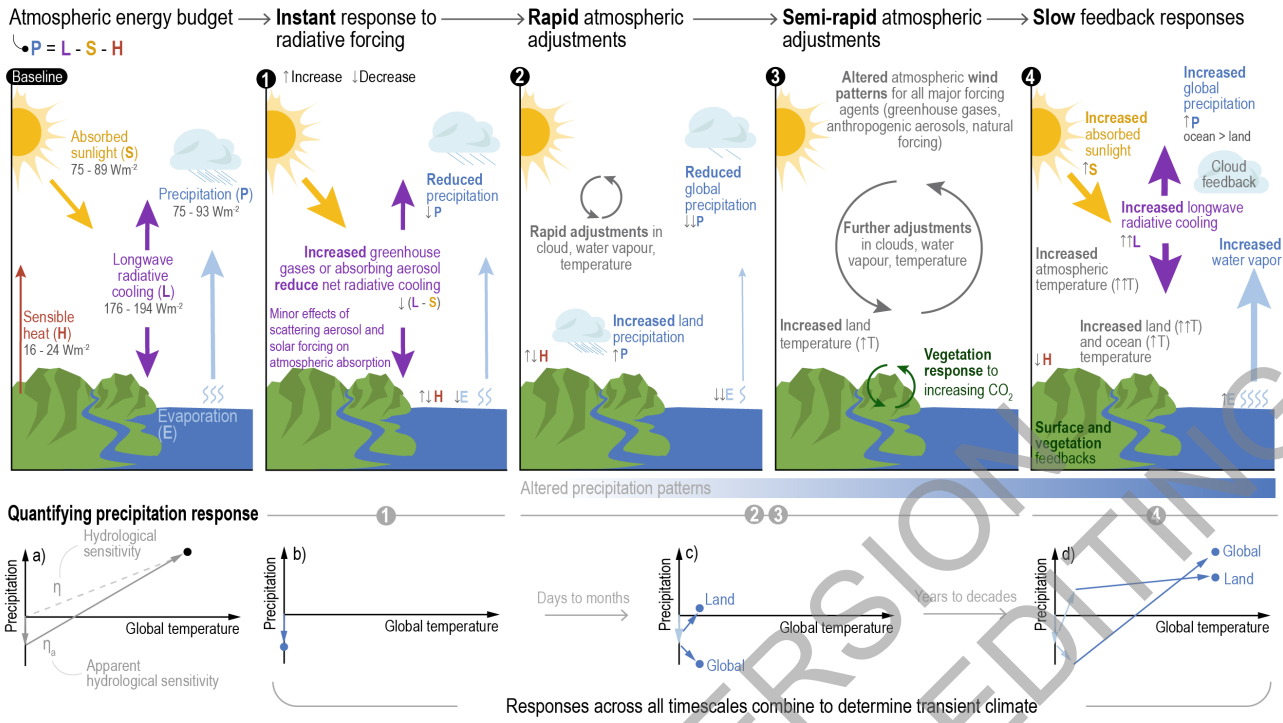

Figure 8.3: Schematic representation of fast and slow responses of the atmospheric energy balance and global precipitation to radiative forcing. The atmospheric energy budget ('baseline' panel) responds instantaneously to radiative forcings (1), leading to rapid atmospheric adjustments (2) and slower semi-rapid adjustments involving the land surface and vegetation that further modify atmospheric circulation patterns (3). This slow precipitation response to global mean surface air temperature (4) is quantified as the hydrological sensitivity, η, and the total precipitation response, including initial rapid adjustments, is termed the apparent hydrological sensitivity, η_a (a). The slow precipitation response over land and ocean develops over time (b-d). Large, filled arrows (in panels from 'baseline' to 4) depict fluxes or circulation change while small arrows (1-4) denote increases (↑) or decreases (↓) in variables (P is precipitation; L is atmospheric longwave radiative cooling, S is solar radiation absorption by the atmosphere; H is sensible heat flux; E is surface evaporative heat flux and T is temperature). (Adapted from Allan et al., 2020, Chapter 7 Figure 7.2 and Figure 8.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

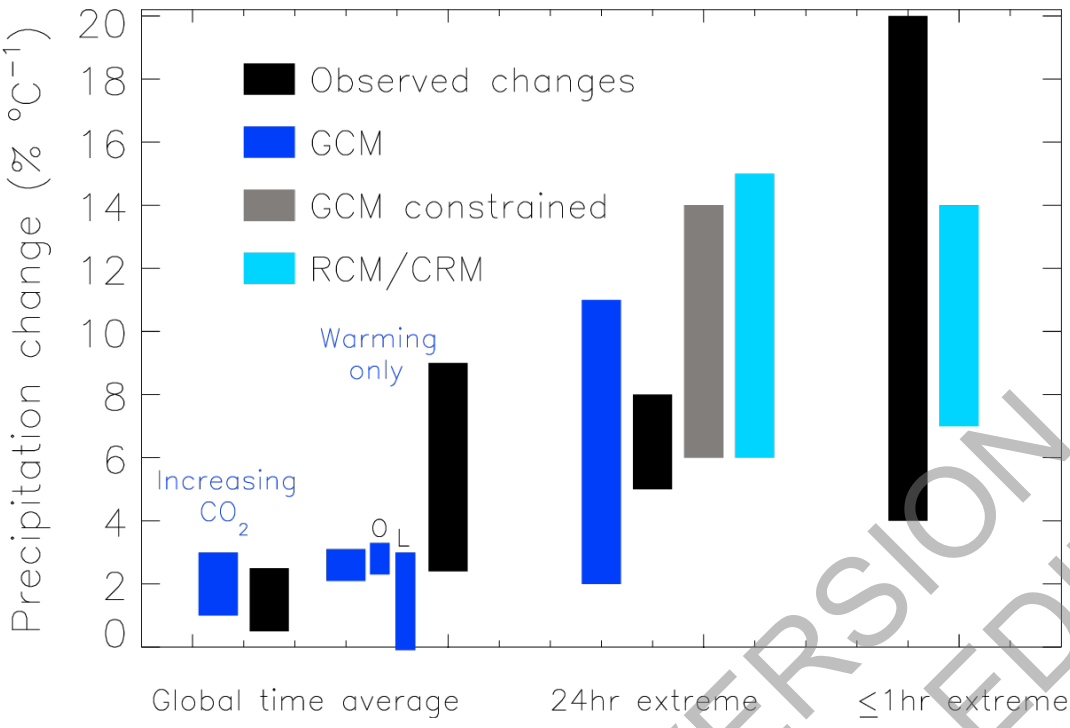

Figure 8.4: Estimate (5-95% range) of the increase in precipitation and its extremes with global mean surface warming. Global time averaged precipitation changes (left) are based on responses to increasing CO_2 (apparent hydrological sensitivity, η_a) and the temperature-dependent component (hydrological sensitivity, η) based on GCM experiments and including the land (L) and ocean (O) components (Fläschner et al., 2016; Richardson et al., 2018; Samset et al., 2018; Pendergrass, 2020; Rehfeld et al., 2020) and observational estimates (GPCP/HadCRUTv4.6) using trends (1988-2014) as a proxy for η_a and interannual variability as a proxy for η with 90% confidence range accounting for statistical uncertainty only (Adler et al., 2017; Allan et al., 2020). For extreme precipitation, assessment is for 24 hour 99.9th percentile or annual maximum extremes from GCMs (Fischer and Knutti, 2015; Pendergrass et al., 2015; Borodina et al., 2017; Pfahl et al., 2017; Sillmann et al., 2017), regional climate models (RCMs) (Bao et al., 2017), an observationally constrained tropical estimate (O'Gorman, 2012) and estimates from observed changes (Westra et al., 2013; Donat et al., 2016; Borodina et al., 2017; Sun et al., 2020; Zeder and Fischer, 2020). For hourly and sub-hourly extremes observed changes (Barbero et al., 2017; Guerreiro et al., 2018) and high resolution models including RCM and cloud resolving models (CRMs) are assessed (Ban et al., 2015; Prein et al., 2017; Haerter and Schlemmer, 2018; Hodnebrog et al., 2019; Lenderink et al., 2019). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

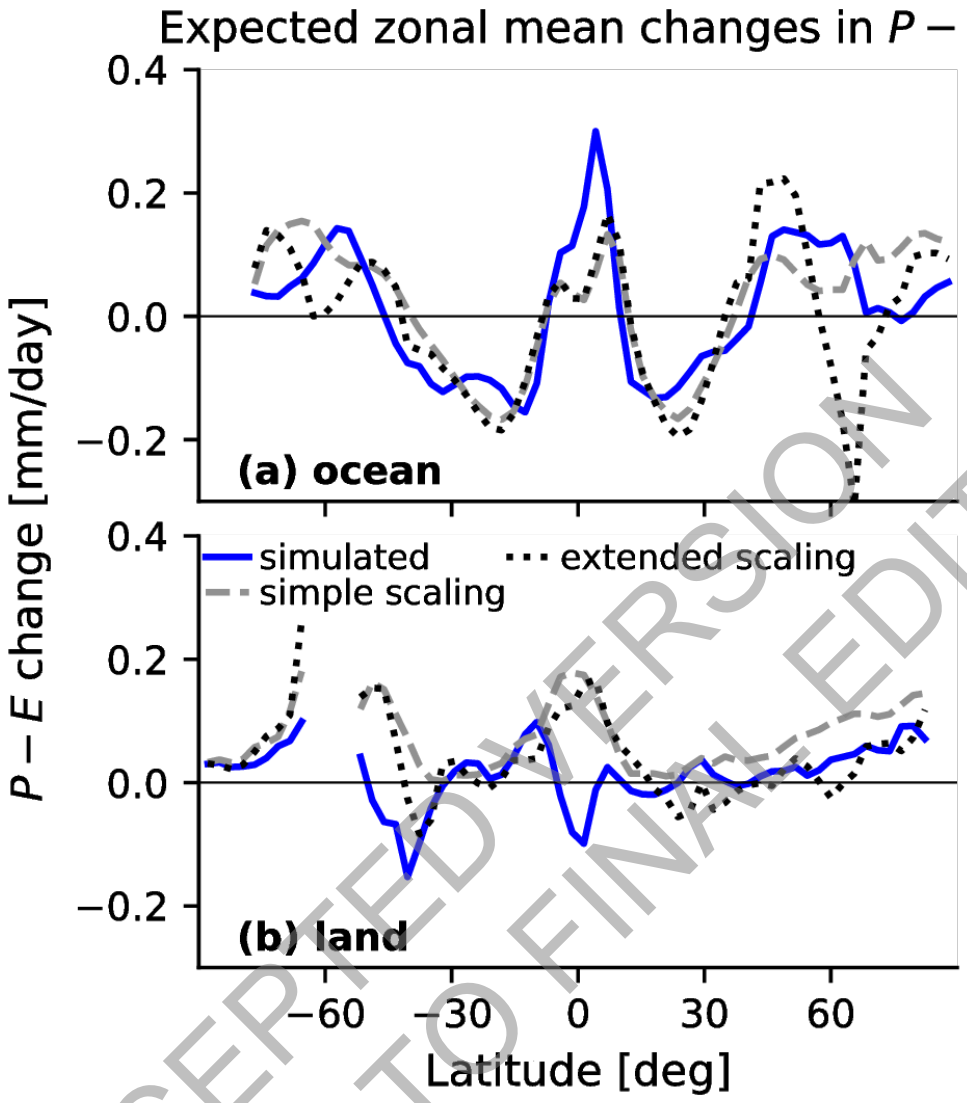

Figure 8.5: **Zonally-averaged annual mean changes in precipitation minus evaporation (P-E) over (a) ocean and (b) land between the historical (1995–2014) and SSP2-4.5 (2081–2100) CMIP6 simulations (blue lines, an average of the CanESM5 and MRI-ESM2-0 models).** Dashed lines show estimated P-E changes using a simple thermodynamic scaling (Held and Soden, 2006); dotted lines show estimates using an extended scaling (Byrne and O'Gorman, 2016). All curves have been smoothed in latitude using a three grid-point moving-average filter. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

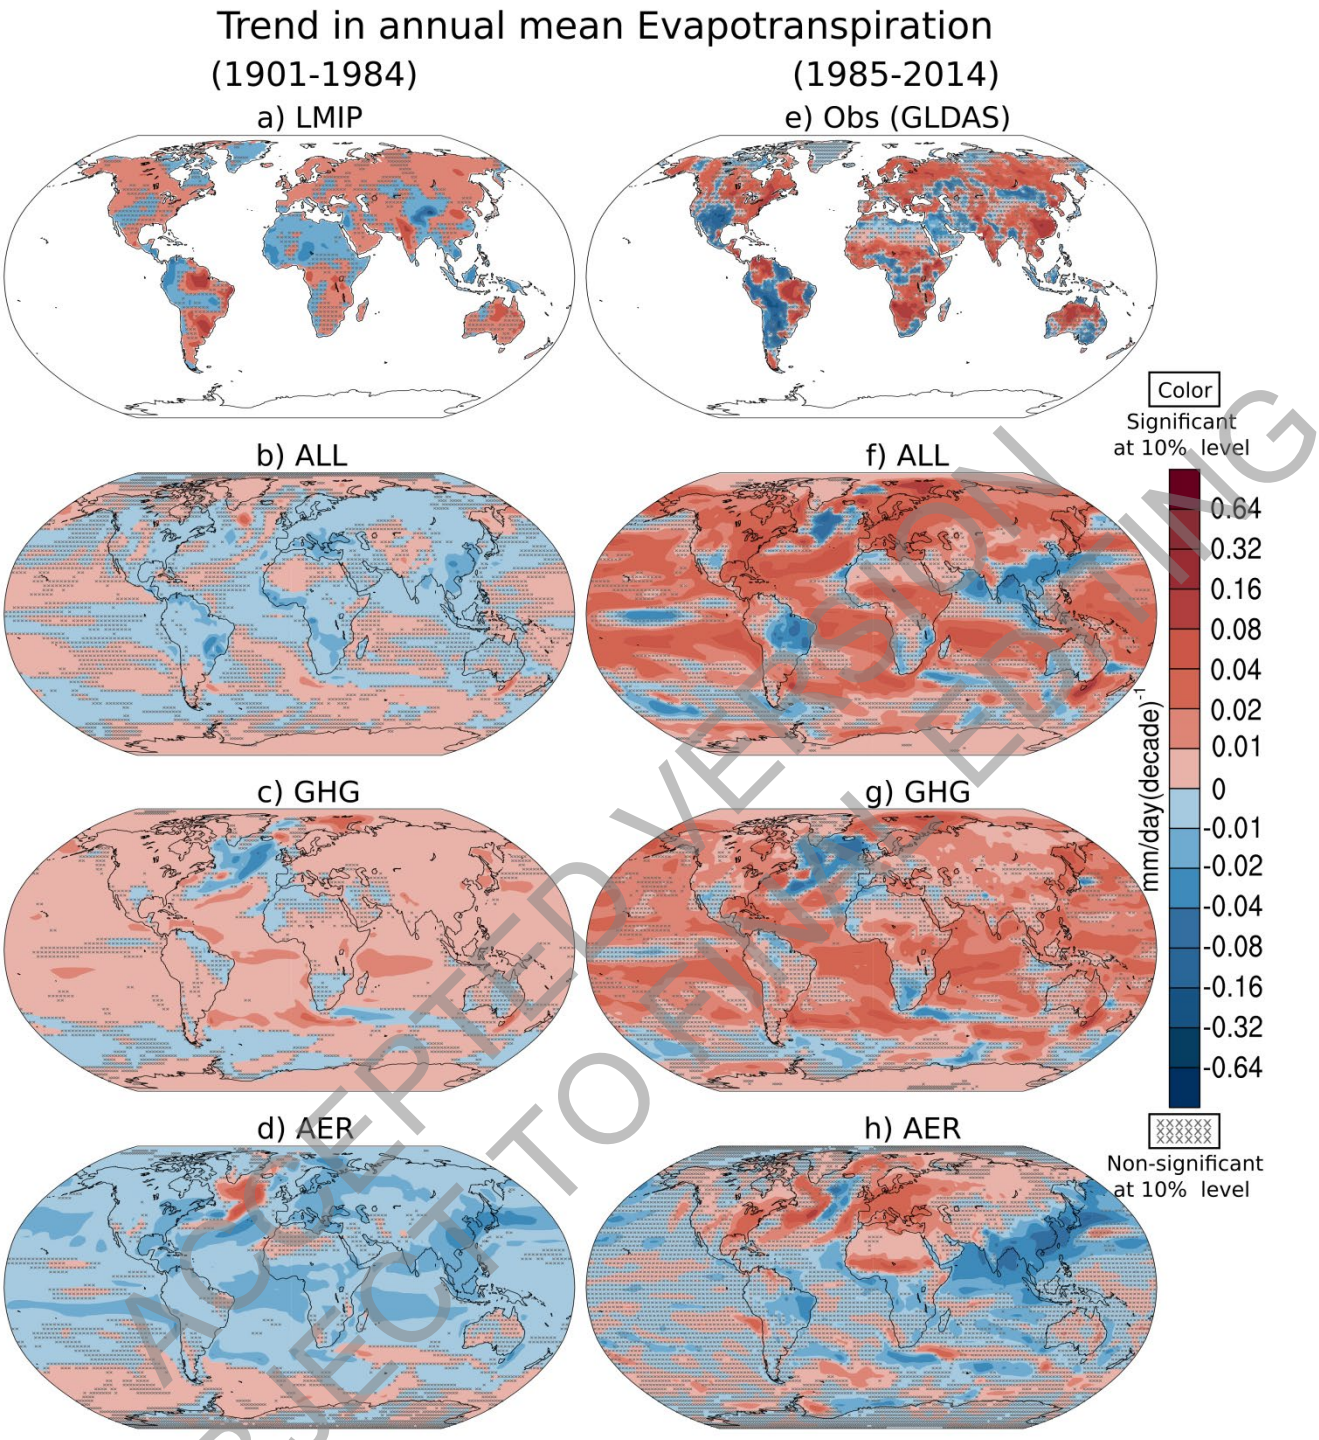
Box 8.1, Figure 1: Northern hemisphere surface downward radiation anomalies (Wm^{-2} ; a) and precipitation anomalies (mm/day ; b) for 1951–2014 for summer season (May–September) monsoon region (Polson et al. et al., 2014) from CMIP6 DAMIP experiments. Observed solar radiation anomalies are from GEBA global data from 1961-2014 (Wild et al., 2017) and observed precipitation anomalies are from GPCC and CRU. CMIP6 multi-model mean anomalies are from all-forcings (ALL), greenhouse gas forcing (GHG) and anthropogenic aerosol forcing (AER) experiments. Anomalies are with respect to 1961–1990 and smoothed with a 11-year running mean. Red shading shows the ensemble spread of ALL forcing experiment (5%–95% range). Models are masked to the GPCC data set. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING



Box 8.1, Figure 2: Schematic depiction of the atmospheric effects of light absorbing aerosols on convection and cloud formation: (A) without and (B) with the presence of absorbing aerosols in the planetary boundary layer. The dashed and solid blue lines correspond to the vertical temperature profiles in the absence and presence of the absorbing aerosol layer, respectively, and the solid and dashed red lines denote the dry and moist adiabats, respectively. Absorbing aerosols result in an increasing temperature in the atmosphere but a reduced temperature at the surface. The reduced surface temperature and the increased temperature aloft lead to a larger negative energy associated with convective inhibition (-) and a higher convection condensation level (CCL) under the polluted conditions. On the other hand, the absorbing aerosol layer induces a larger convective available potential energy (+) above CCL, facilitating more intensive vertical development of clouds, if lifting is sufficient to overcome the larger convective inhibition. From (Wang et al., 2013).

Figure 8.7: Linear trends in annual mean precipitation (mm/day per decade) for 1901-1984 (left) and 1985-2014 (right): (a & e) observational dataset, and the CMIP6 multi model ensemble mean historical simulations driven by, (b & f) all radiative forcings, (c & g) GHG only radiative forcings, (d & h) aerosol only radiative forcings experiment. Colour shades without grey cross correspond to the regions exceeding 10 % significant level. Grey crosses correspond to the regions not reaching the 10% statistical significant level. Nine CMIP6-DAMIP models have been used having at least 3 members. The ensemble mean is weighted per each model on the available and used members. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Figure 8.8: Linear trends in annual mean evapotranspiration (mm/day per decade) for 1901-1984 (left) and 1985-2014 (right): (a & e) LMIP and observational dataset, and the CMIP6 multi model ensemble mean historical simulations driven by, (b & f) all radiative forcings, (c & g) GHG only radiative forcings, (d & h) aerosol only radiative forcings experiment. Colour shade without grey cross correspond to the regions exceeding 10 % significant level. Grey crosses correspond to the regions not reaching the 10% statistically significant level. Nine CMIP6-DAMIP models have been used having at least 3 members. The ensemble mean is weighted per each model on the available and used members. GLDAS is not available over the early 20th century so was replaced by a multi-model off-line reconstruction, LMIP, which is consistent with GLDAS over the recent period but may be less reliable over the early 20th century given larger uncertainties in the atmospheric forcings. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

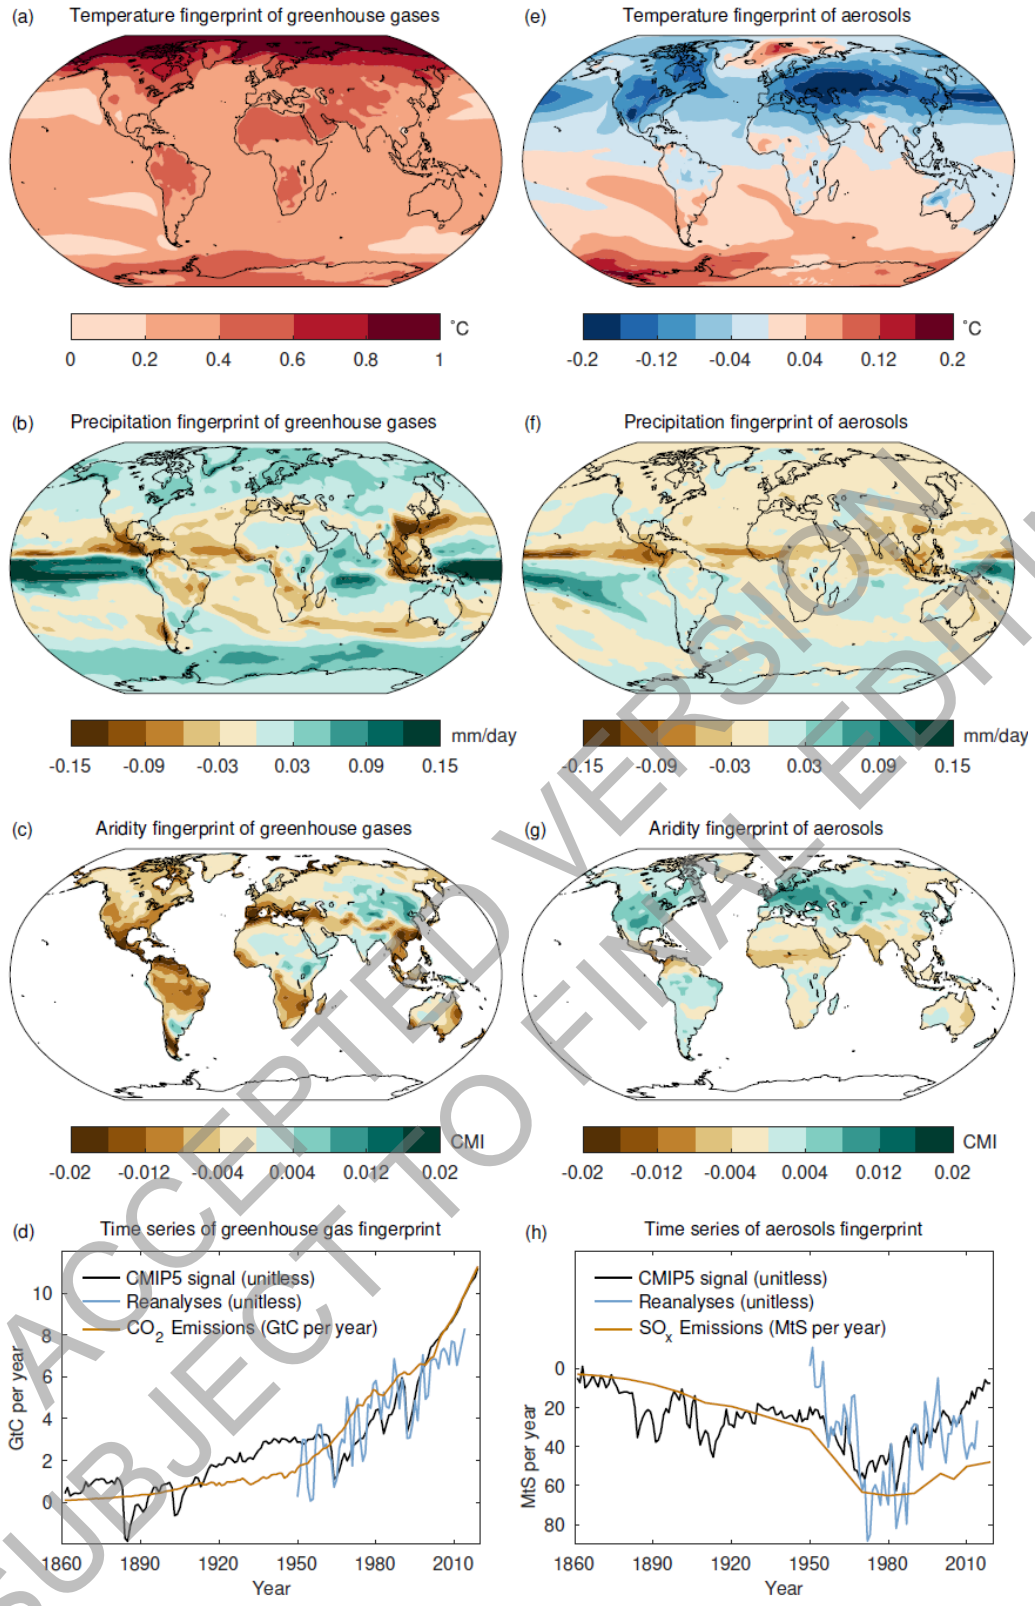

Figure 8.9: Spatial expressions (a-c; e-g) of the leading multivariate fingerprints of temperature (˚C), precipitation (mm/day), and aridity (CMI; the Climate Moisture Index) in CMIP5 historical simulations and the corresponding temporal evolution in both CMIP5 and reanalysis products (d, h). The first leading fingerprint is associated with greenhouse gas forcing (a-d) and the second leading fingerprint is associated with aerosol forcing (e-h). CMI is a dimensionless aridity indicator that combines precipitation and atmospheric evaporative demand. Figure after (Bonfils et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

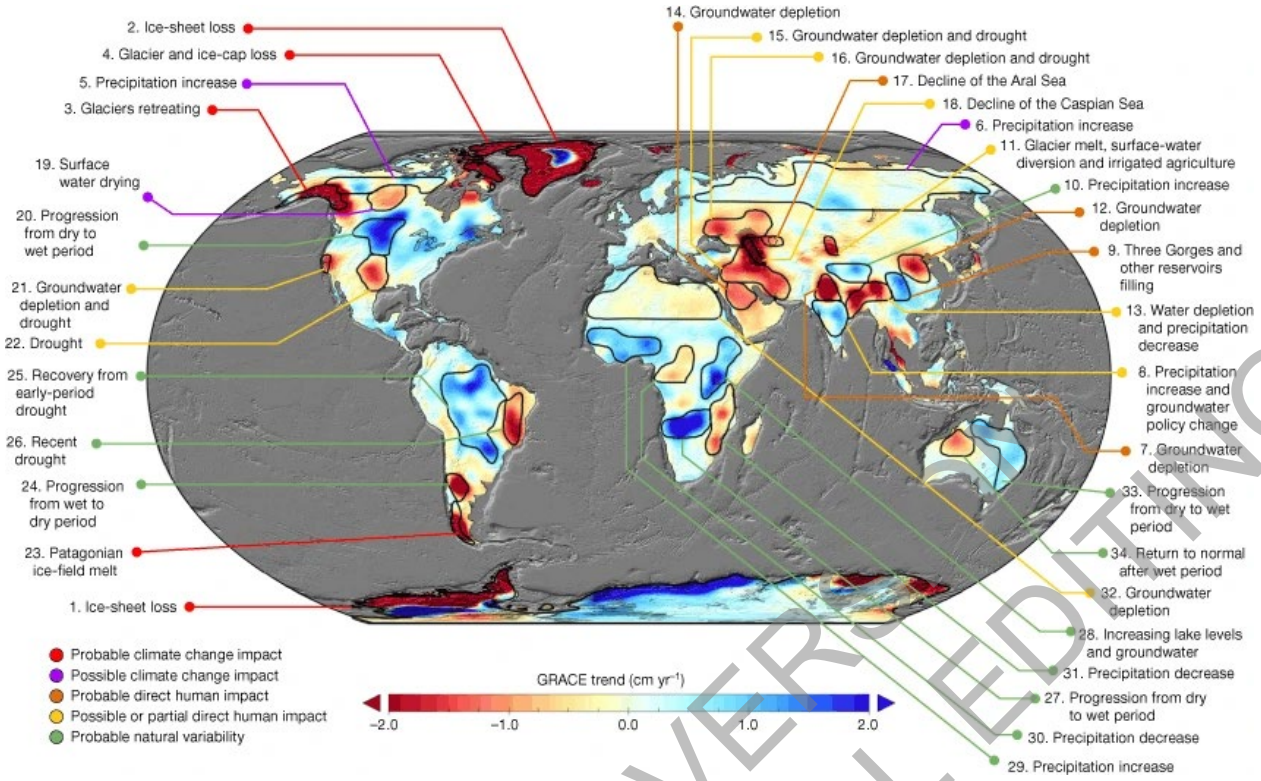

Figure 8.10: Trends in Terrestrial Water Storage (TWS) (in centimetres per year) obtained on the basis of GRACE observations from April 2002 to March 2016. The cause of the trend in each outlined study region is briefly explained and colour-coded by category. The trend map was smoothed with a 150-km-radius Gaussian filter for the purpose of visualization; however, all calculations were performed at the native 3° resolution of the data product. Figure from Rodell et al. (2018). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

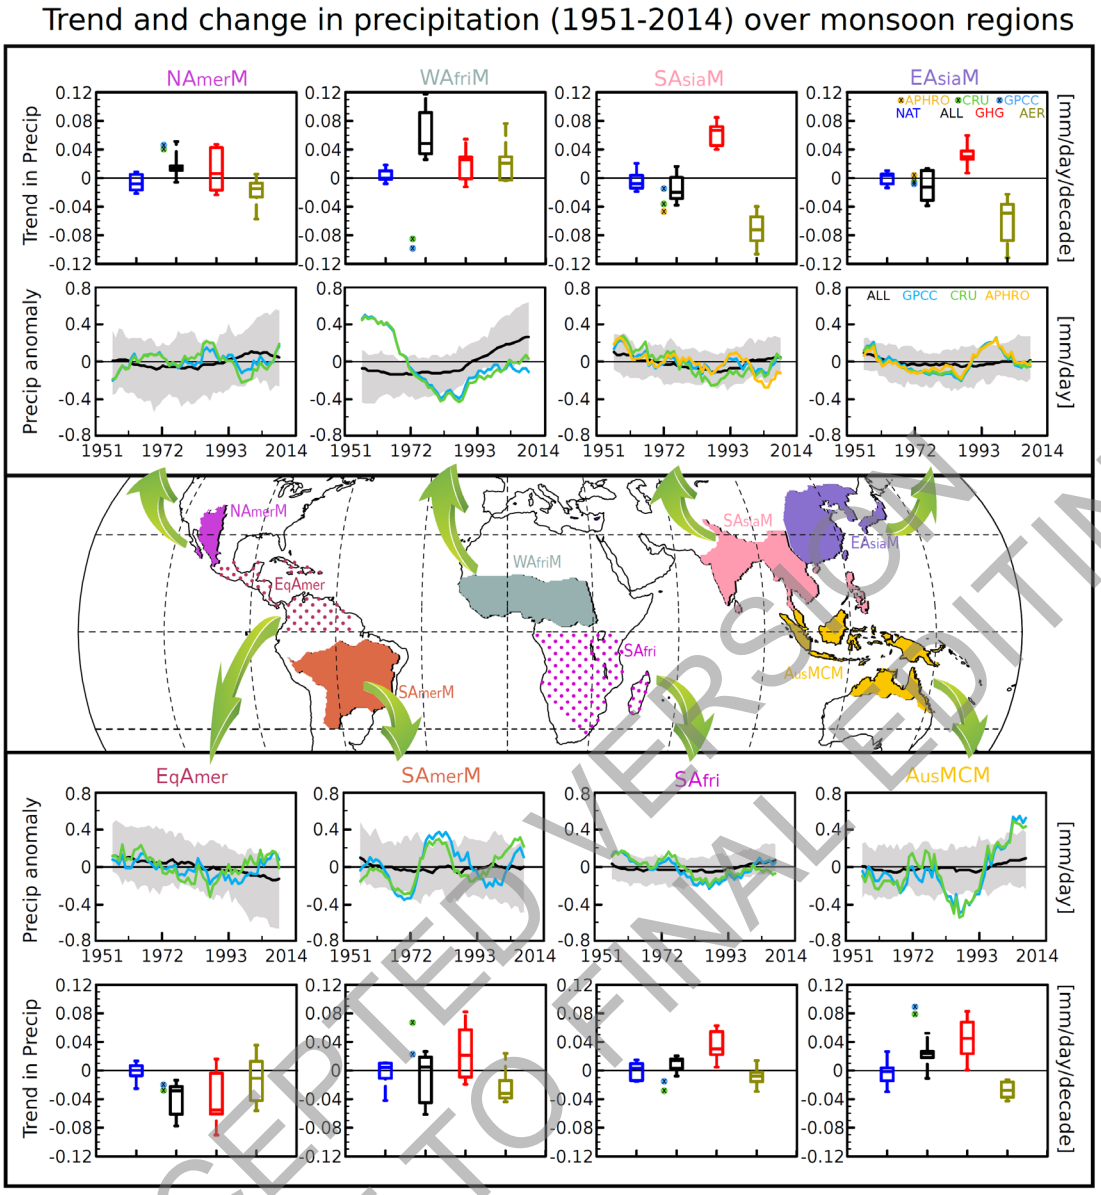
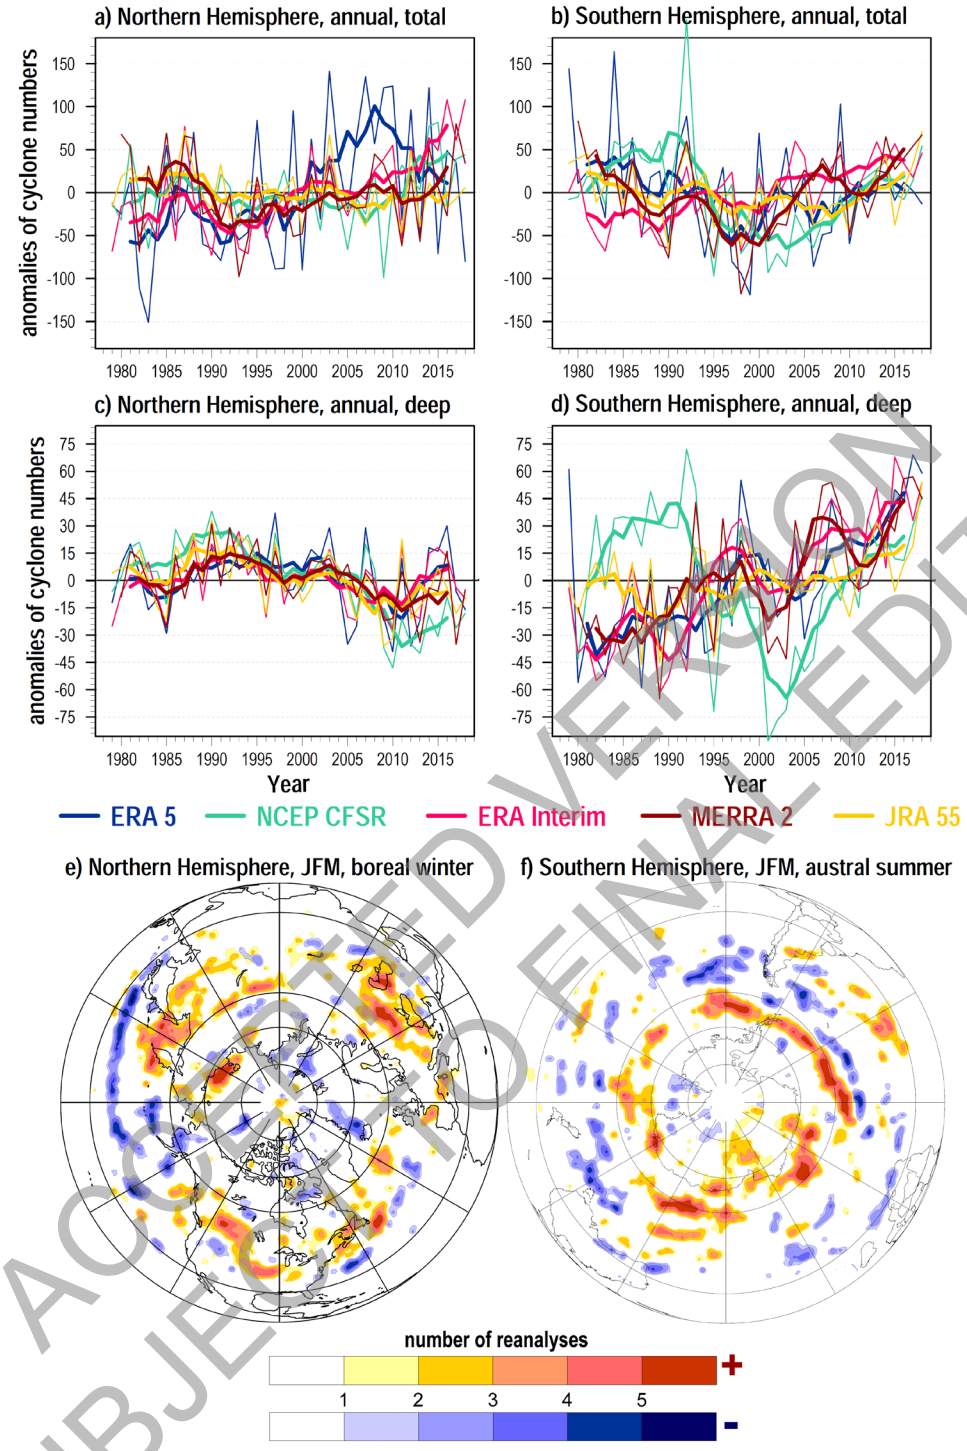
ACCEPTED VERSION SUBJECT TO FINAL EDITING





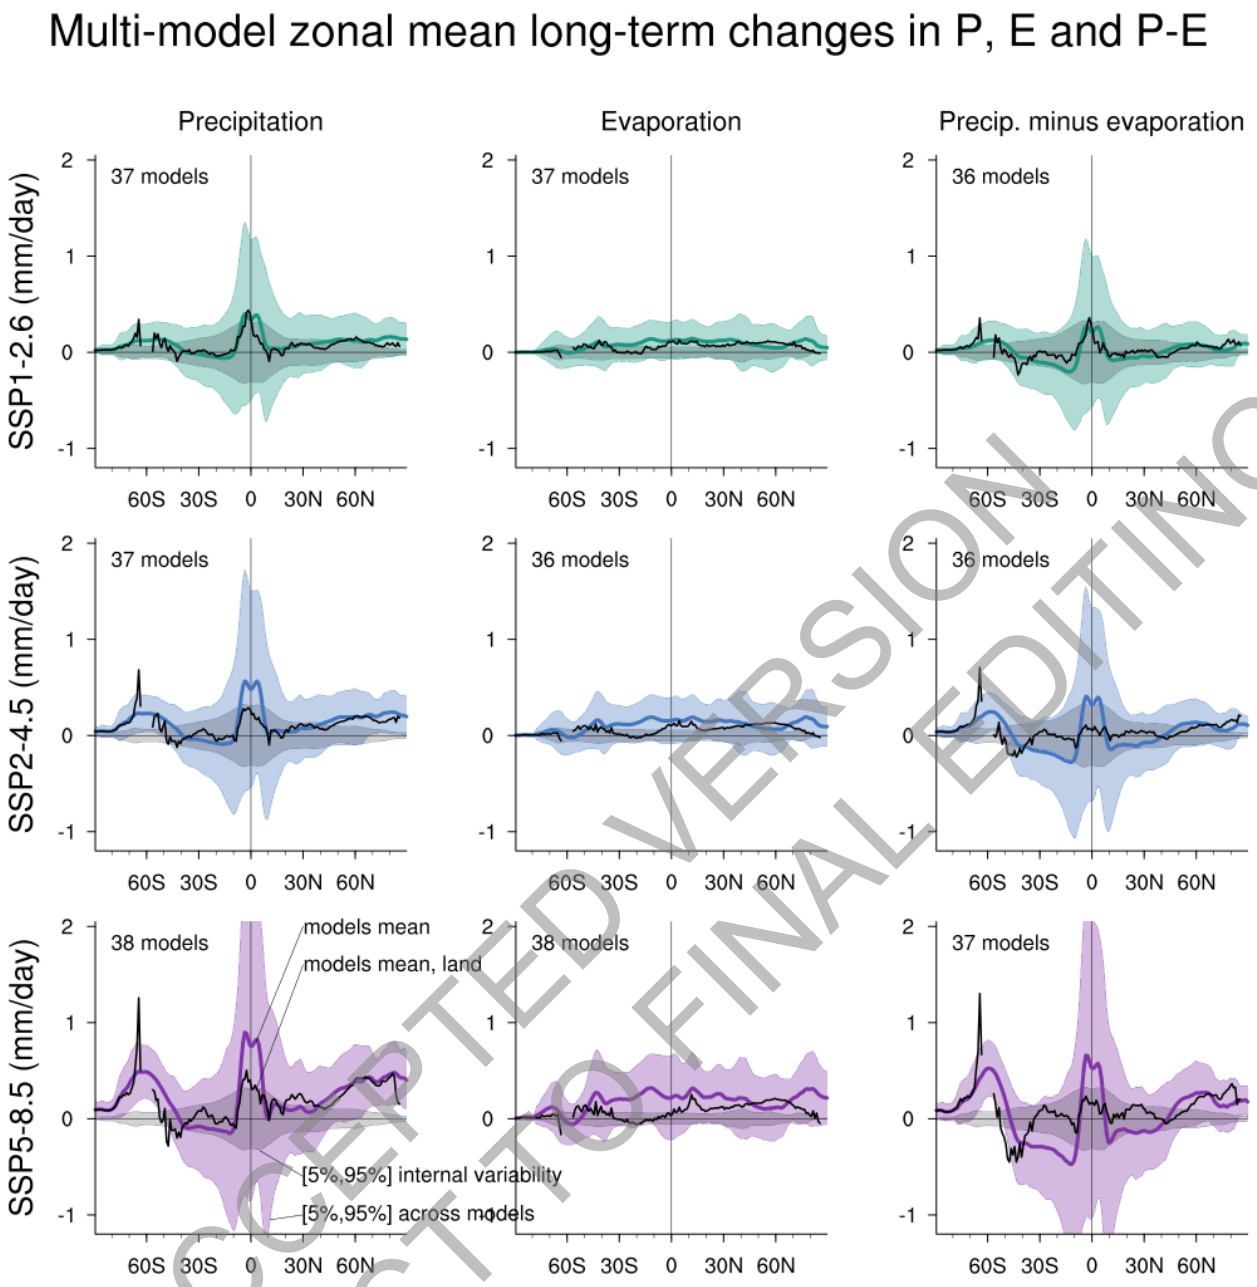


Figure 8.11: Regional monsoon precipitation changes from observations and model attribution. Precipitation changes during 1951-2014 are shown as least-square linear trends in box-whisker plots (first and fourth rows) over the six regional monsoons, i.e., North American monsoon (NAmerM, Jul-Aug-Sep), West African monsoon (WAfriM, Jun-Jul-Aug-Sep), South and Southeast Asian monsoon (SAsiaM, Jun-Jul-Aug-Sep), East Asian monsoon (EAsiaM, Jun-Jul-Aug), South American monsoon (SAmerM, Dec-Jan-Feb), Australian and Maritime Continent monsoon (AusMCM, Dec-Jan-Feb), and over the two land domains (i.e. equatorial America (EqAmer, Jun-Jul-Aug) and South Africa (SAfri, Dec-Jan-Feb), as identified in the map shown in the middle and as described in Annex V. Precipitation changes are computed from observations and from DAMIP CMIP6 experiments over the historical period with all-forcing (ALL), GHG-only forcing (GHG), Aerosol-only (AER) and Natural (NAT) forcings prescribed. Observations are based on the CRU (light green) and GPCC (light blue) datasets and the APHRODITE (light orange) dataset for SAsiaM and EAsiaM. CMIP6 simulations are taken from nine CMIP6 models contributing to DAMIP, with at least 3 members. Ensembles are weight-averaged for the respective model ensemble size. Observed trends are shown as colored cirles and the simulated trends from the CMIP6 multi-model experiments are shown as box-whisker plots. Precipitation anomaly time-series are shown in the second and third row. The thick black line is the multi-model ensemble-mean precipitation anomaly time-series from the ALL experiment and the grey shading shows the spread across the multi-model ensembles. A 11-year running mean has been applied on the precipitation anomaly time-series prior to calculating the multi-model ensemble mean. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

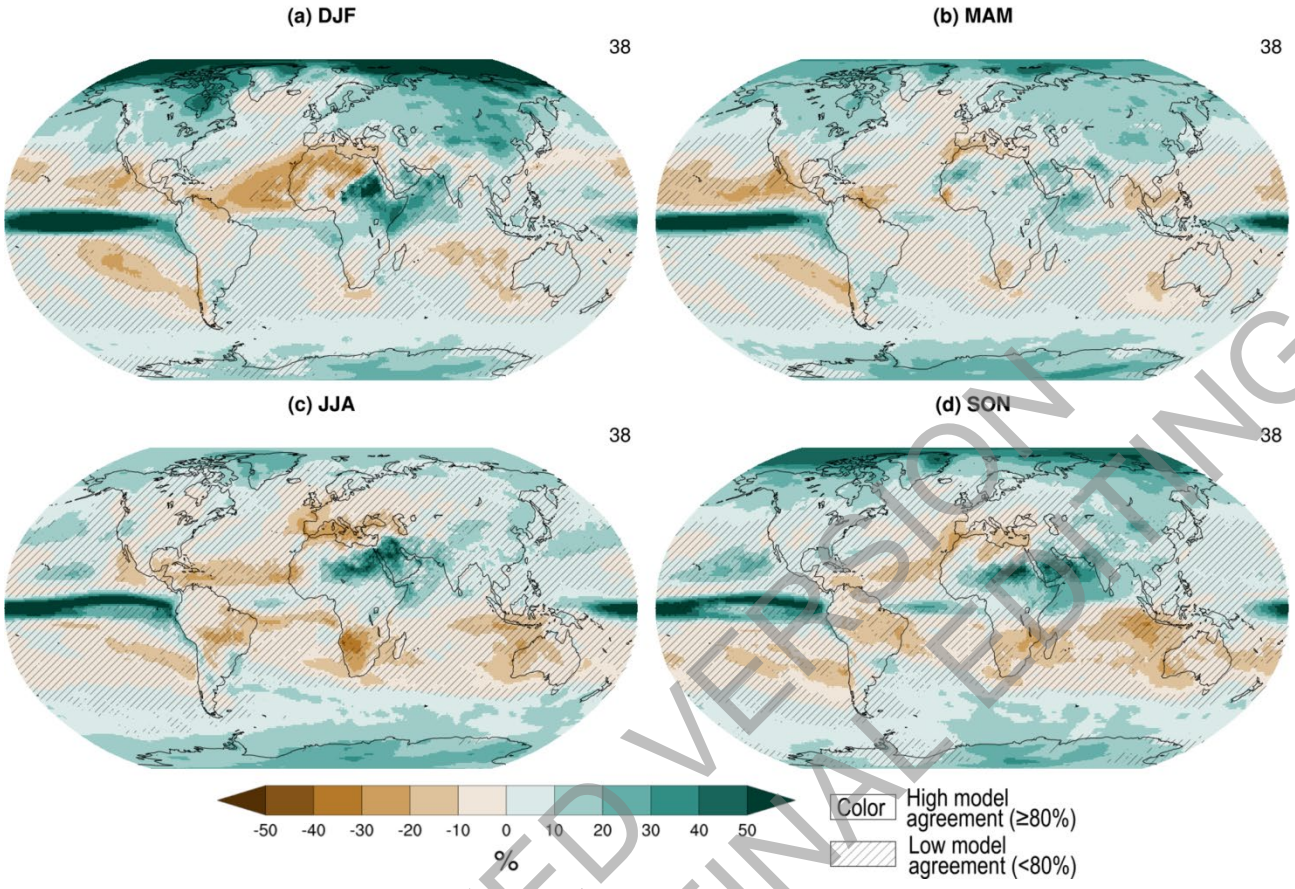
Figure 8.12: Annual anomalies (with respect to the reference period 1979-2018) of the total number of extratropical cyclones (a, c) and of the number of deep cyclones (<980hPa) (b, d) over the Northern (a, b) and the Southern (c, d) Hemispheres in different reanalyses (shown in colors in the legend). Note different vertical scales for panels (a), (b) and (c), (d). Thin lines indicate annual anomalies and bold lines indicate 5-yr running averages. (e), (f) The number of reanalyses (out of five) simultaneously indicating statistically significant (90% level) linear trends of the same sign during 1979–2018 for JFM over the Northern Hemisphere (e) and over the Southern Hemisphere (f). Updated from (Tilinina et al., 2013). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Figure 8.13: Zonal and annual mean projected long-term changes in the atmospheric water budget. Zonal and annual mean projected changes (mm/day) in P (precipitation, left column), E (evaporation, middle column), and P-E (right column) over both land and ocean areas (thick line) and over land only (dashed line) averaged across 36 to 38 CMIP6 models in the SSP1-2.6 (a,b), SSP2-4.5 (c,d) and SSP5-8.5 (e,f) scenario, respectively. Shading denotes confidence intervals estimated from the CMIP6 ensemble under a normal distribution hypothesis. Color shading denotes changes over both land and ocean. Grey shading represents internal variability derived from the pre-industrial control simulations. All changes are estimated for 2081-2100 relative to the 1995-2014 base period. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).



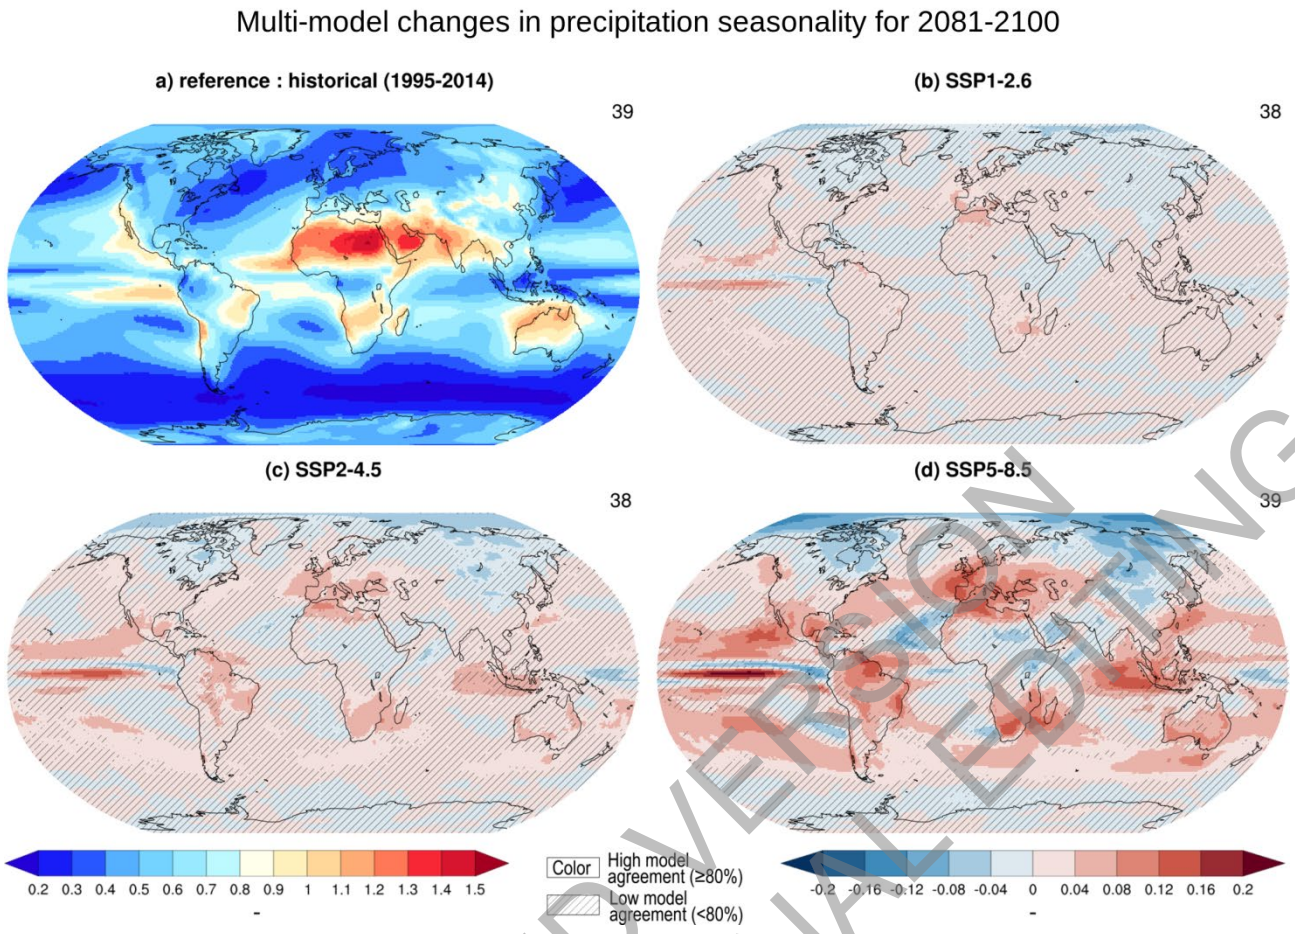


Figure 8.14: Projected long-term relative changes in seasonal mean precipitation. Global maps of projected relative changes (%) in seasonal mean of precipitation averaged across 29 CMIP6 models in the SSP2-4.5 scenario. All changes are estimated for 2081-2100 relative to the 1995-2014 base period. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

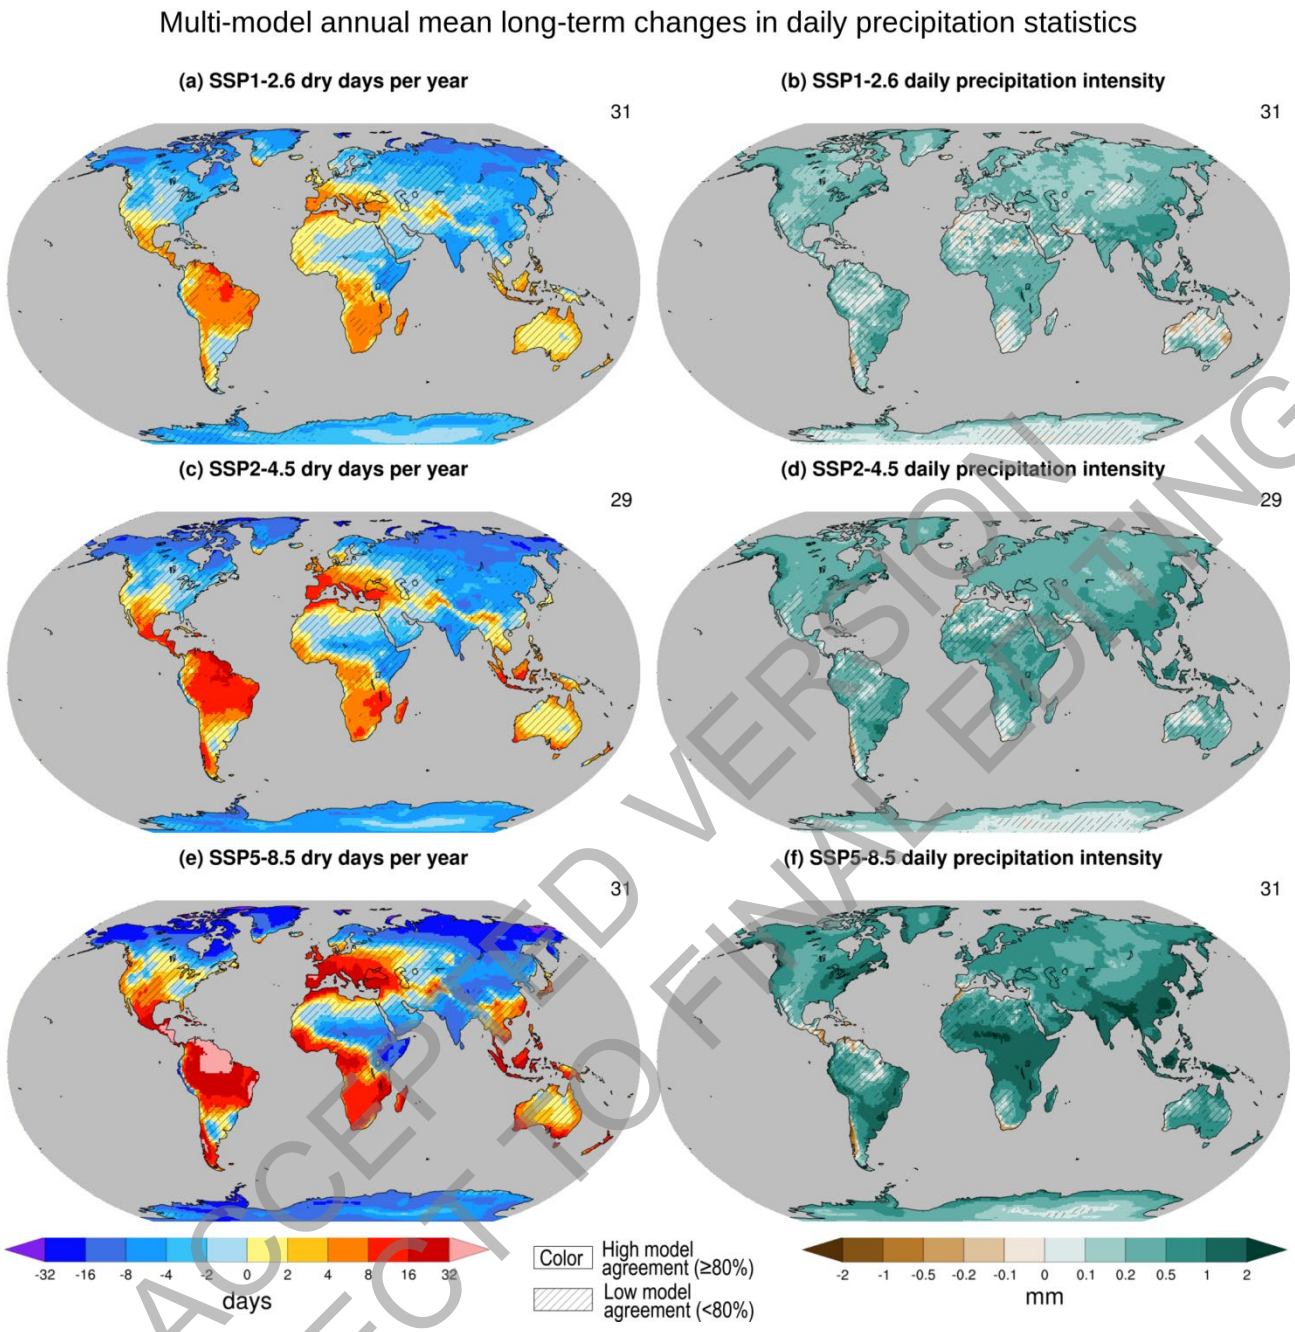
ACCEPTED VERSION SUBJECT TO FINAL EDITING

Box 8.2, Figure 1: Projected long-term changes in precipitation seasonality. Global maps of projected changes in precipitation seasonality (simply defined as the sum of the absolute deviations of mean monthly rainfalls from the overall monthly mean, divided by the mean annual rainfall as in Walsh and Lawler, 1981) averaged across 31 to 33 CMIP6 models in the SSP1-2.6 (b), SSP2-4.5 (c) and SSP5-8.5 (d) scenario respectively. The simulated 1995-2014 climatology is shown in panel (a). All changes are estimated in 2081-2100 relative to 1995-2014. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING



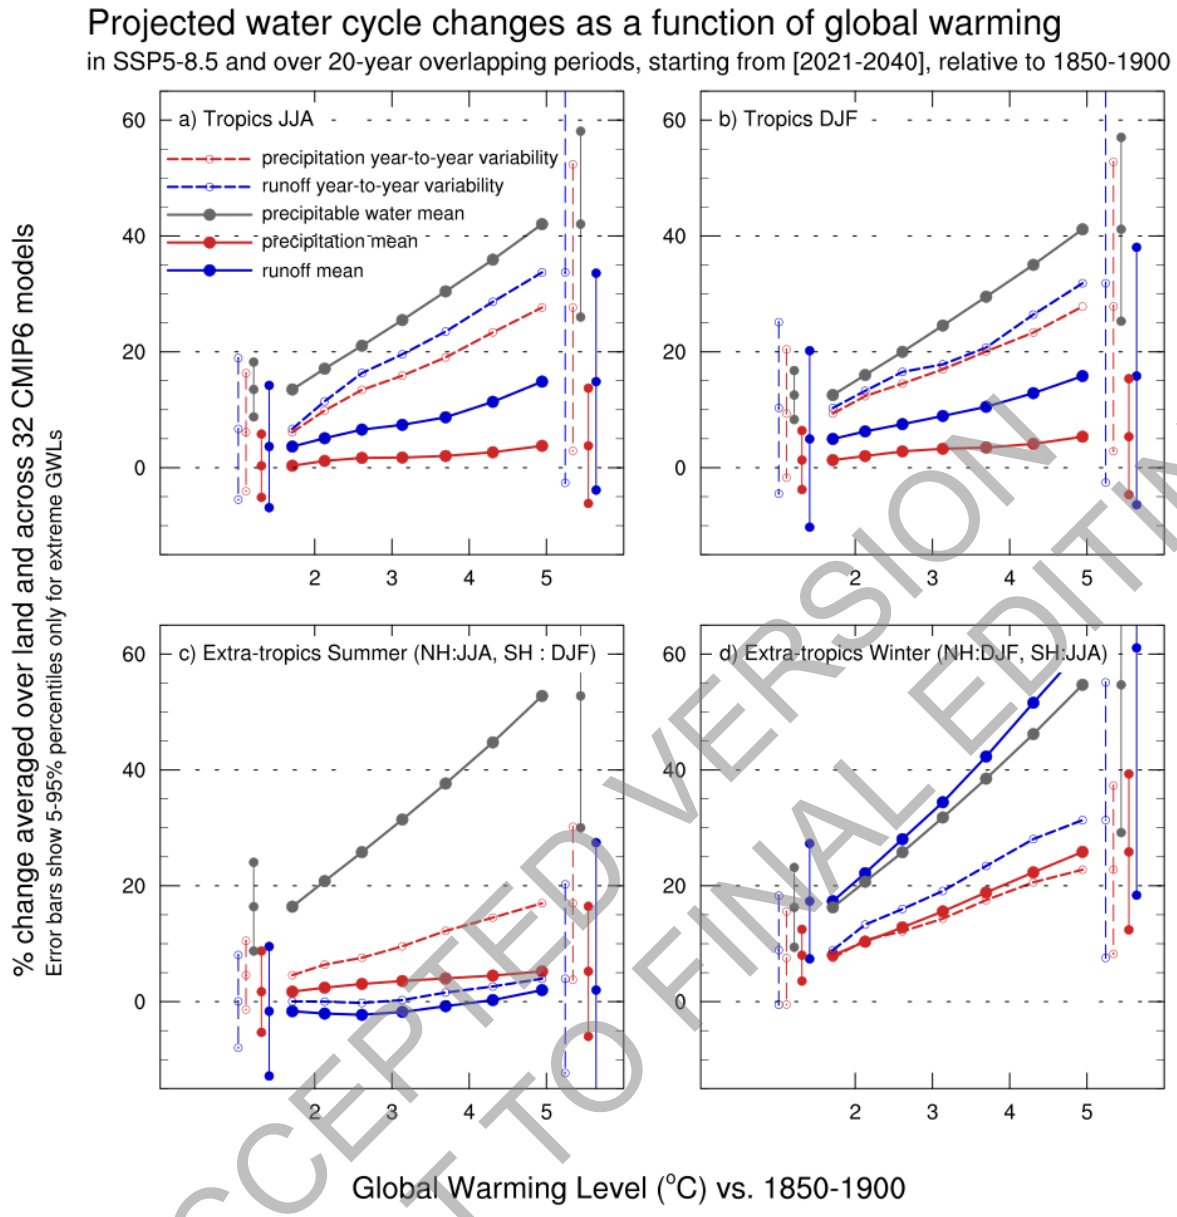


Figure 8.15: Projected long-term relative changes in daily precipitation statistics. Global maps of projected seasonal mean relative changes (%) in the number of dry days (i.e. days with less than 1 mm of rain) and daily precipitation intensity (in mm/day, estimated as the mean daily precipitation amount at wet days - i.e., days with intensity above 1 mm/day) averaged across CMIP6 models in the SSP1-2.6 (a,b), SSP2-4.5 (c,d) and SSP5-8.5 (e,f) scenario respectively. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

Figure 8.16: Rate of change in mean and variability across increasing global warming levels. Relative change (%) in seasonal mean total precipitable water (green dashed line), precipitation (red dashed lines), runoff (blue dashed lines), as well as in standard deviation of precipitation (red solid lines) and runoff (blue solid lines) averaged over extra-tropical land in (a) summer and (b) winter, and tropical land in (c) JJA and (d) DJF as a function of global-mean surface temperature for the CMIP6 multi-model mean across the SSP5-8.5 scenario. Extra-tropical winter refers to DJF for Northern Hemisphere and JJA for Southern Hemisphere (and the reverse for extra-tropical summer). Each marker indicates a 21-year period centered on consecutive decades between 2015 and 2085 relative to the 1995–2014 base period. Precipitation and runoff variability are estimated by their standard deviation after removing linear trends from each time series. Error bars show the 5-95% confidence interval for the warmest 5°C global warming level. Figure adapted from (Pendergrass et al., 2017) and updated with CMIP6 models. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

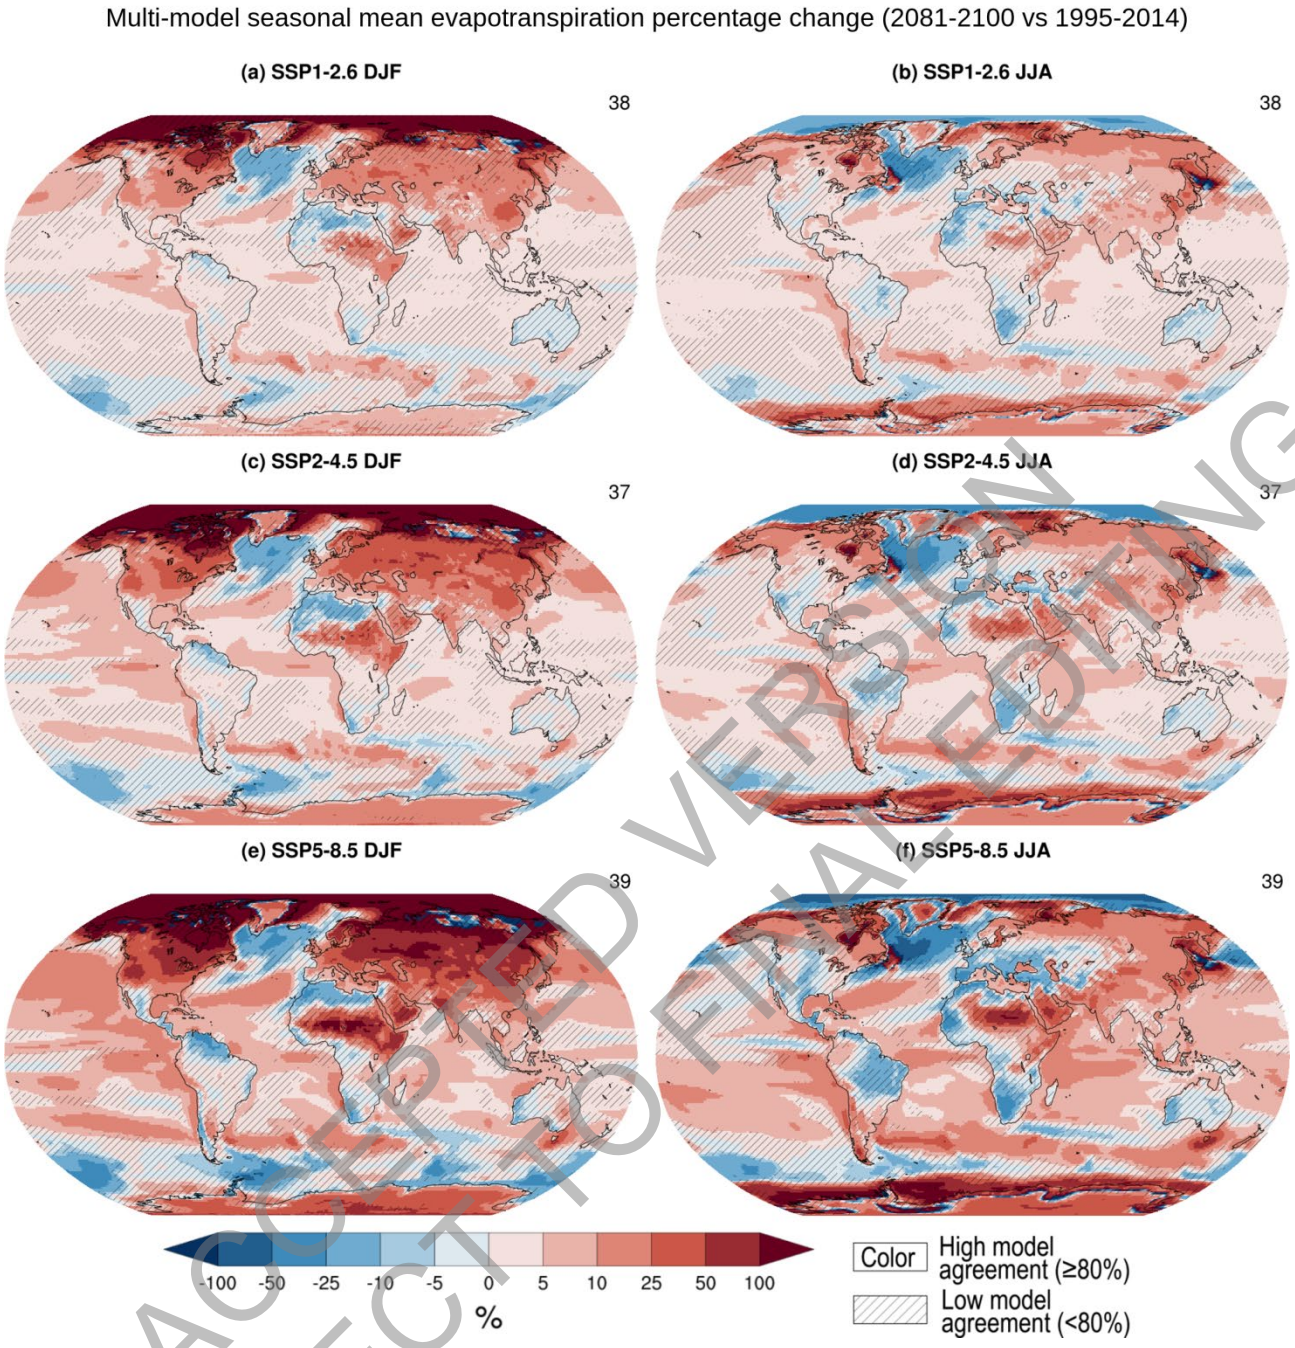

Figure 8.17: Projected long-term relative changes in seasonal mean evapotranspiration. Global maps of projected relative changes (%) in seasonal mean of surface evapotranspiration for DJF (left panels) and JJA (right panels) averaged across 29 or 30 CMIP6 models for SSP1.2-6 (a,b), SSP2-4.5 (c,d) and SSP5-8.5 (e,f) scenario respectively. All changes are estimated in 2081-2100 relative to 1995-2014. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

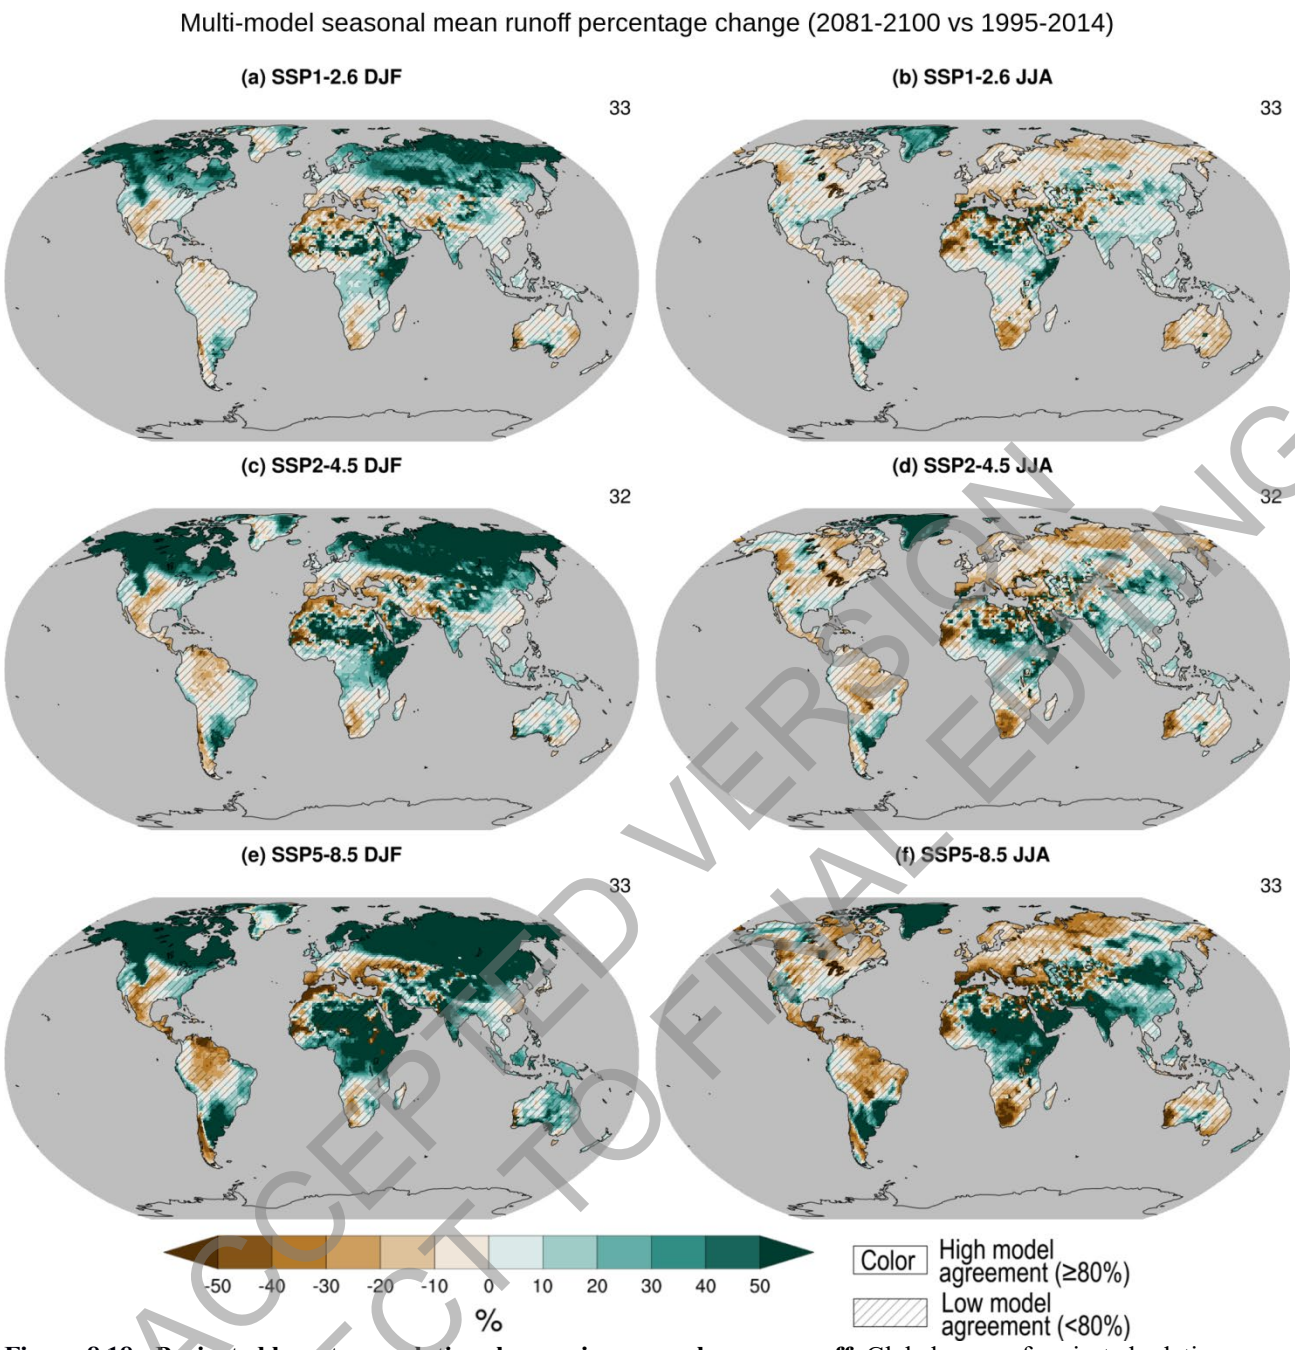

Figure 8.18: Projected long-term relative changes in seasonal mean runoff. Global maps of projected relative change (%) in runoff seasonal mean for DJF (left panels) and JJA (right panels) averaged across CMIP6 models SSP1.2-6 (a,b), SSP2-4.5 (c,d) and SSP5-8.5 (e,f) scenario respectively. All changes are estimated in 2081-2100 relative to 1995-2014. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

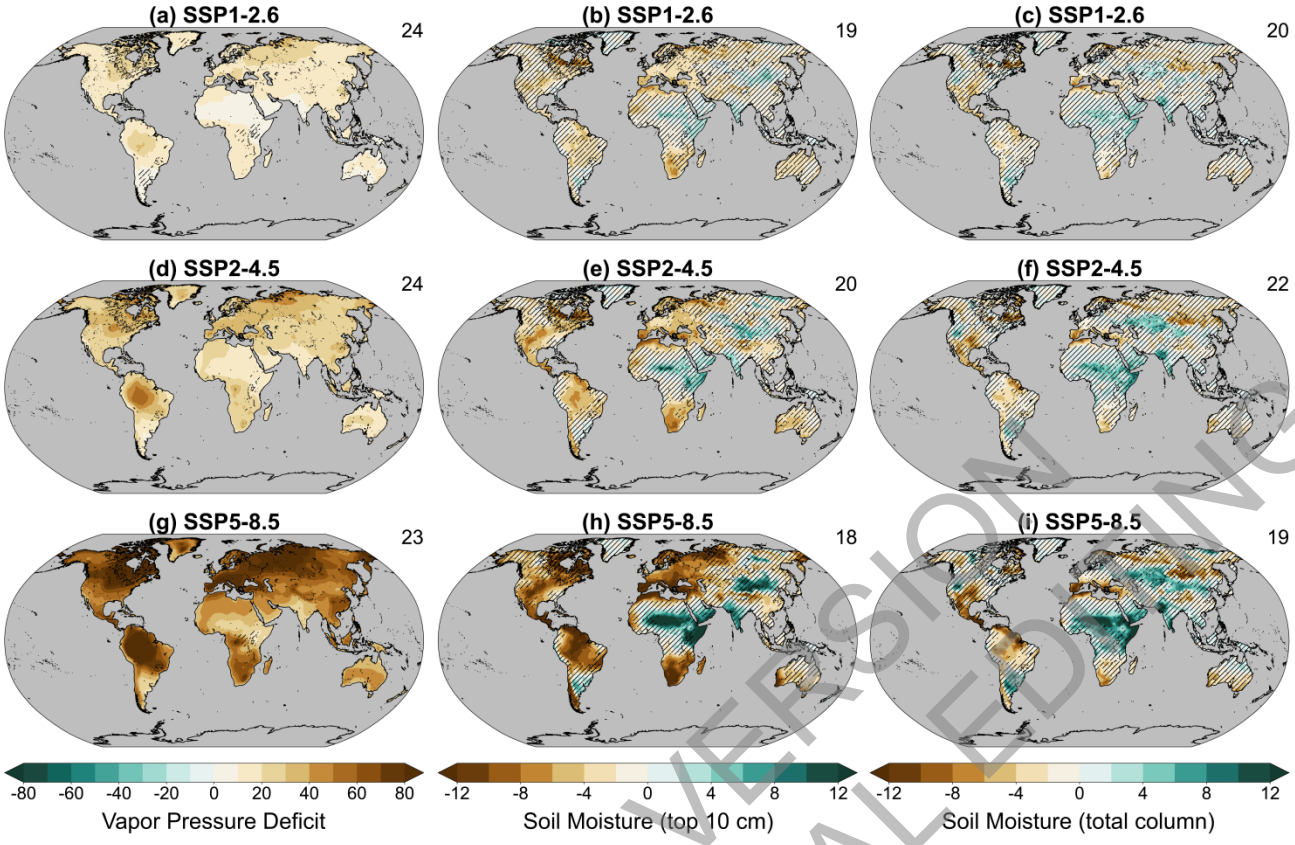
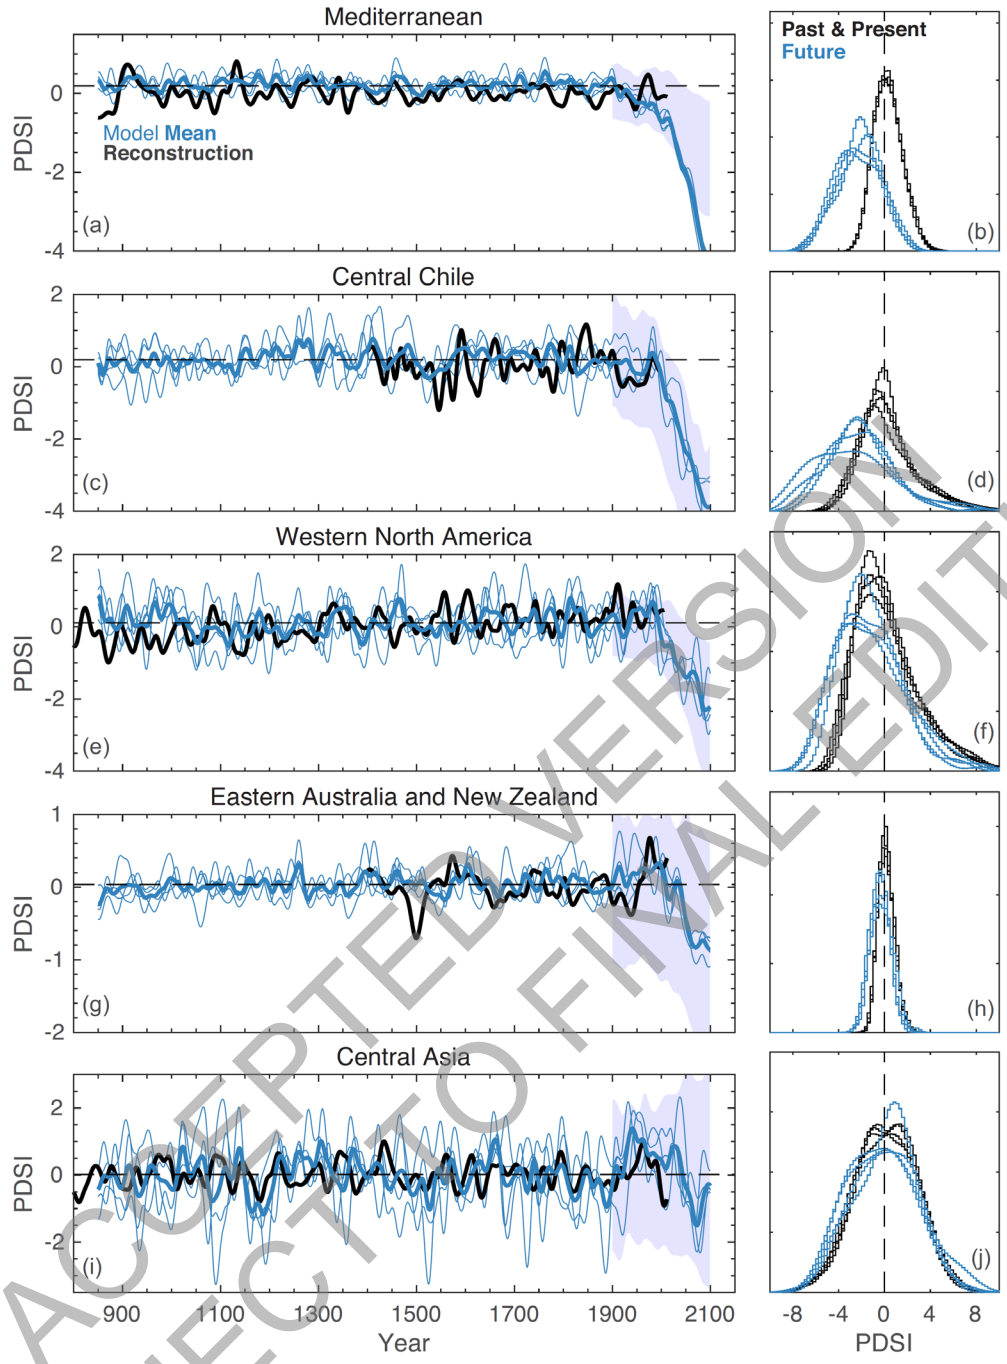
ACCEPTED VERSION SUBJECT TO FINAL EDITING





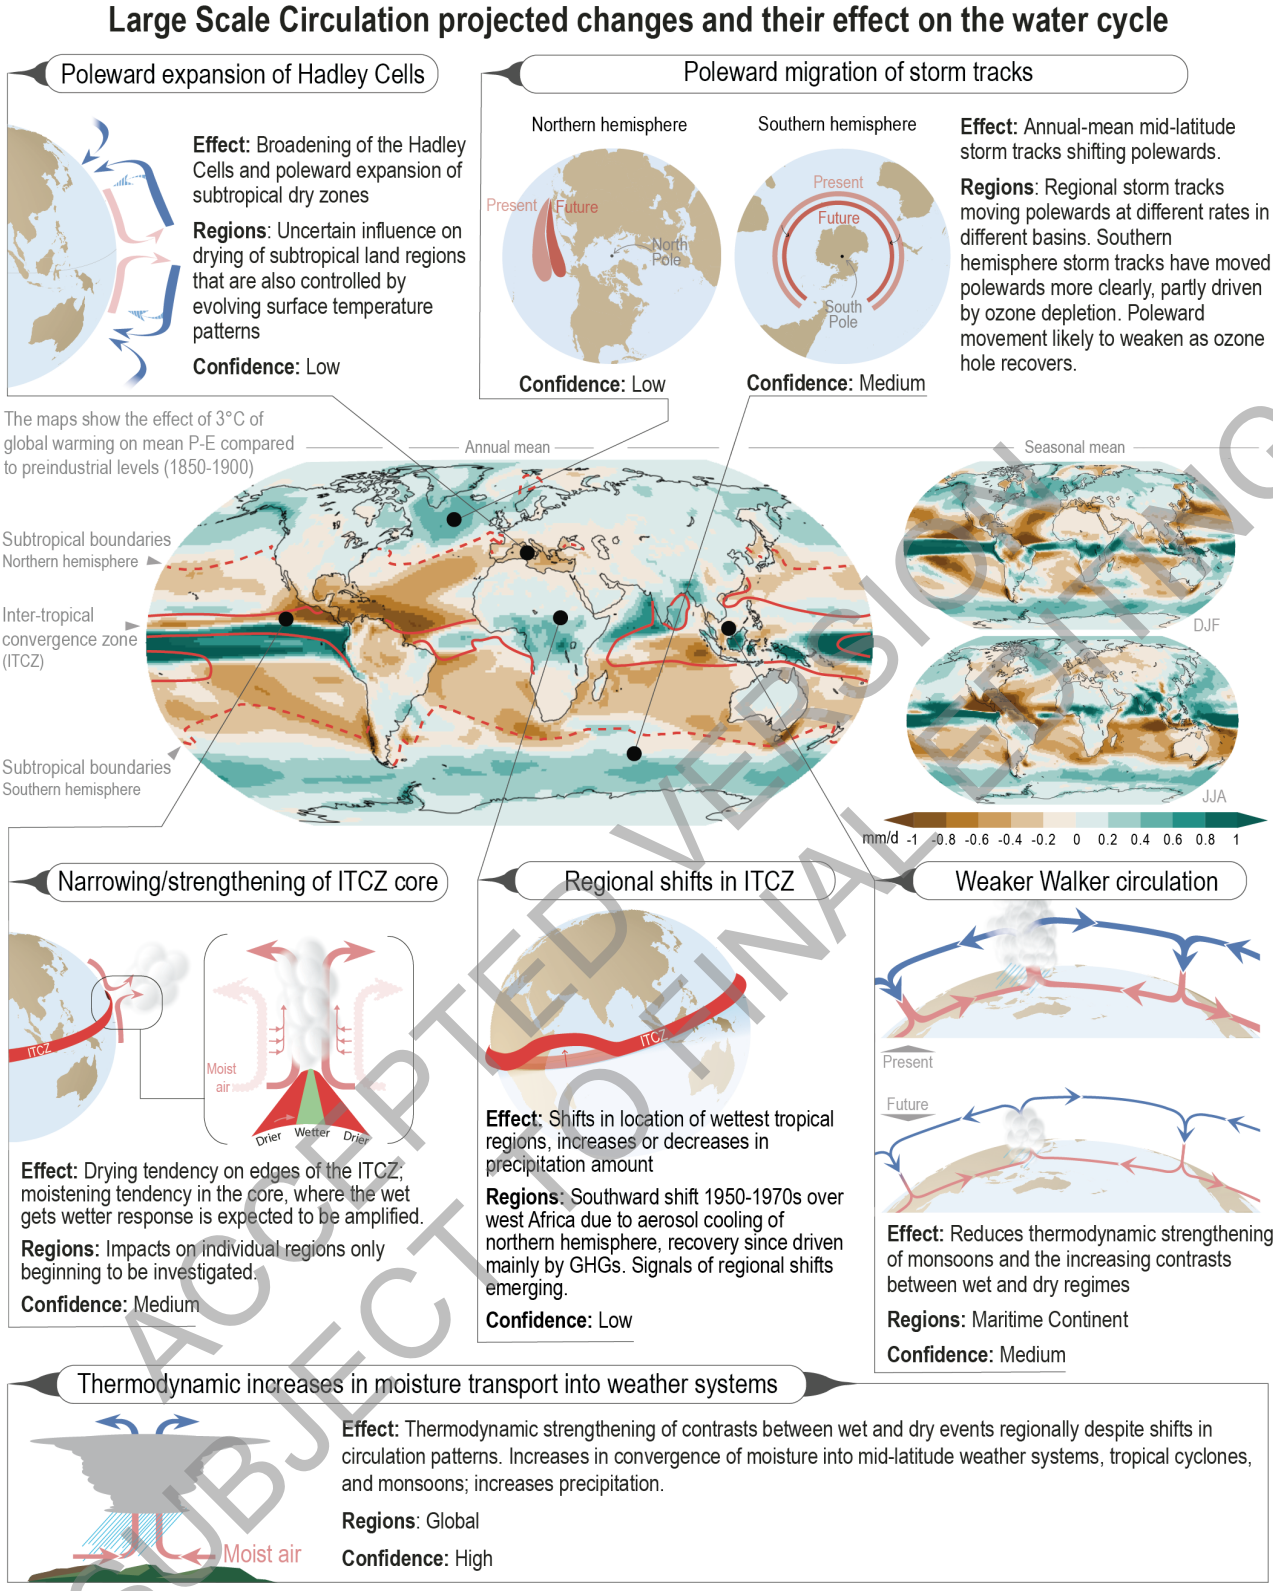


Figure 8.19: Projected long-term relative changes in annual mean soil moisture and vapor pressure deficit. Global maps of projected relative changes (%) in annual mean vapor pressure deficit (left), surface soil moisture (top 10cm, middle) and total column soil moisture (right) from available CMIP6 models for the SSP1.2-6 (a,b,c), SSP2-4.5 (d,e,f) and SSP5-8.5 (g,h,i) scenarios respectively. All changes are estimated for 2081-2100 relative to a 1995-2014 base period. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement ("Robust change"), where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

Figure 8.20: Past-to-future drought variability in paleoclimate reconstructions and models for select regions. On the left (a,c,e,g,i), tree-ring reconstructed Palmer Drought Severity Index (PDSI) series (black line) for the Mediterranean (10°W–45°E, 30°–47°N; Cook et al., 2015, 2016), central Chile (70°–74°W, 32°–37°S; Morales et al., 2020), western North America (117°–124°W, 32°–38°N; Cook et al., 2010; Griffin and Anchukaitis, 2014), Eastern Australia and New Zealand (136°–178°E, 46°–11°S; Palmer et al., 2015), and Central Asia (99°–107°E, 47°–49°N; Pederson et al., 2014; Hessl et al., 2018) plotted in comparison to the past-to-future fully-forced simulations from four ensemble members (thin blue lines) from the NCAR CESM Last Millennium Ensemble (thick blue line = ensemble mean) (Otto-Bliesner et al., 2016) for the same regions. The shaded area represents the range (10th to 90th percentile) of historical and future (RCP8.5) PDSI (Penman-Monteith) simulations from 15 CMIP5 models and 34 ensemble members for the same regions (1900–2100; Cook et al., 2014). On the right (b,d,f,h,i), the distribution of annual PDSI values from the past and present (850 to 2005 CE) (black) is compared to the future distribution (2006 to 2100 CE) (blue). The distributions show each of the four ensemble members from the CESM LME simulations. The future component of the CESM LME follows the RCP8.5 scenario. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Figure 8.21: Schematic depicting large-scale circulation changes and impacts on the regional water cycle. The central figures show precipitation minus evaporation (P-E) changes at 3°C or global warming relative to a 1850-1900 base period (mean of 23 CMIP6 SSP5-8.5 simulations). Annual mean changes (large map) include contours depicting control climate P-E=0 lines with the solid contour enclosing the tropical rain belt region and dashed lines representing the edges of subtropical regions. Confidence levels assess understanding of how large-scale circulation change affect the regional water.

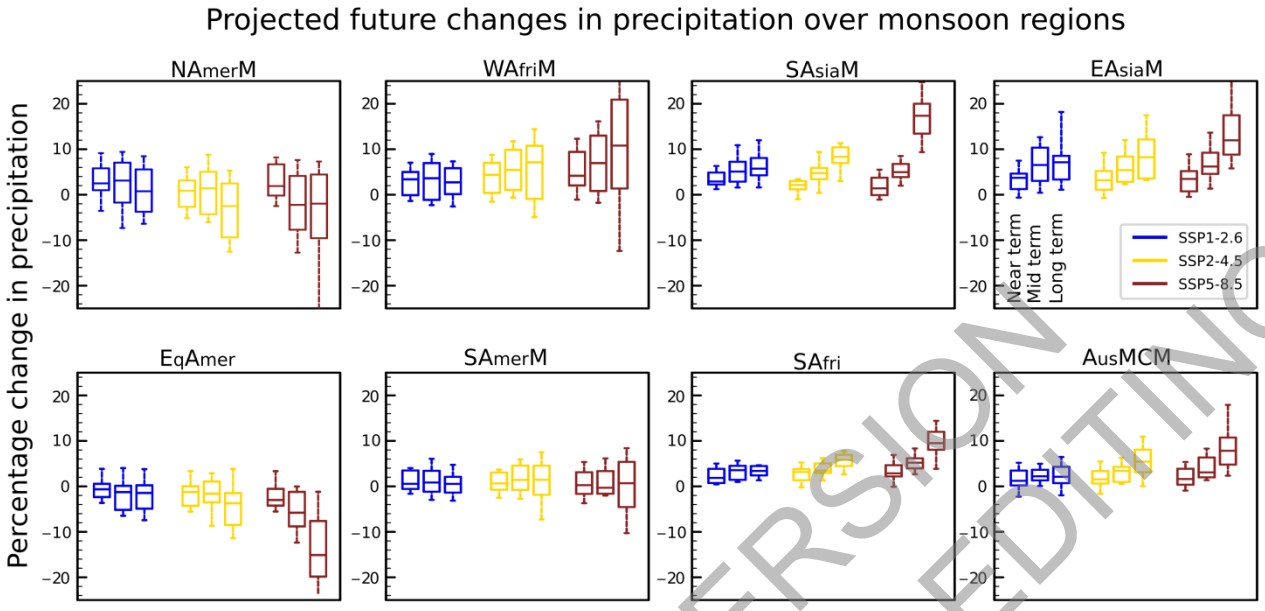

Figure 8.22: Projected regional monsoons precipitation changes. Percentage change in projected seasonal mean precipitation over regional monsoon domains (as defined in Fig 8.11, Section 8.3.2.4 and Annex V) for near-term (2021-2040), mid-term (2041-2060), and long-term (2081-2100) periods based on 24 CMIP6 models and three SSP scenarios (SSP1-2.6, SSP2-4.5 and SSP5-8.5). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

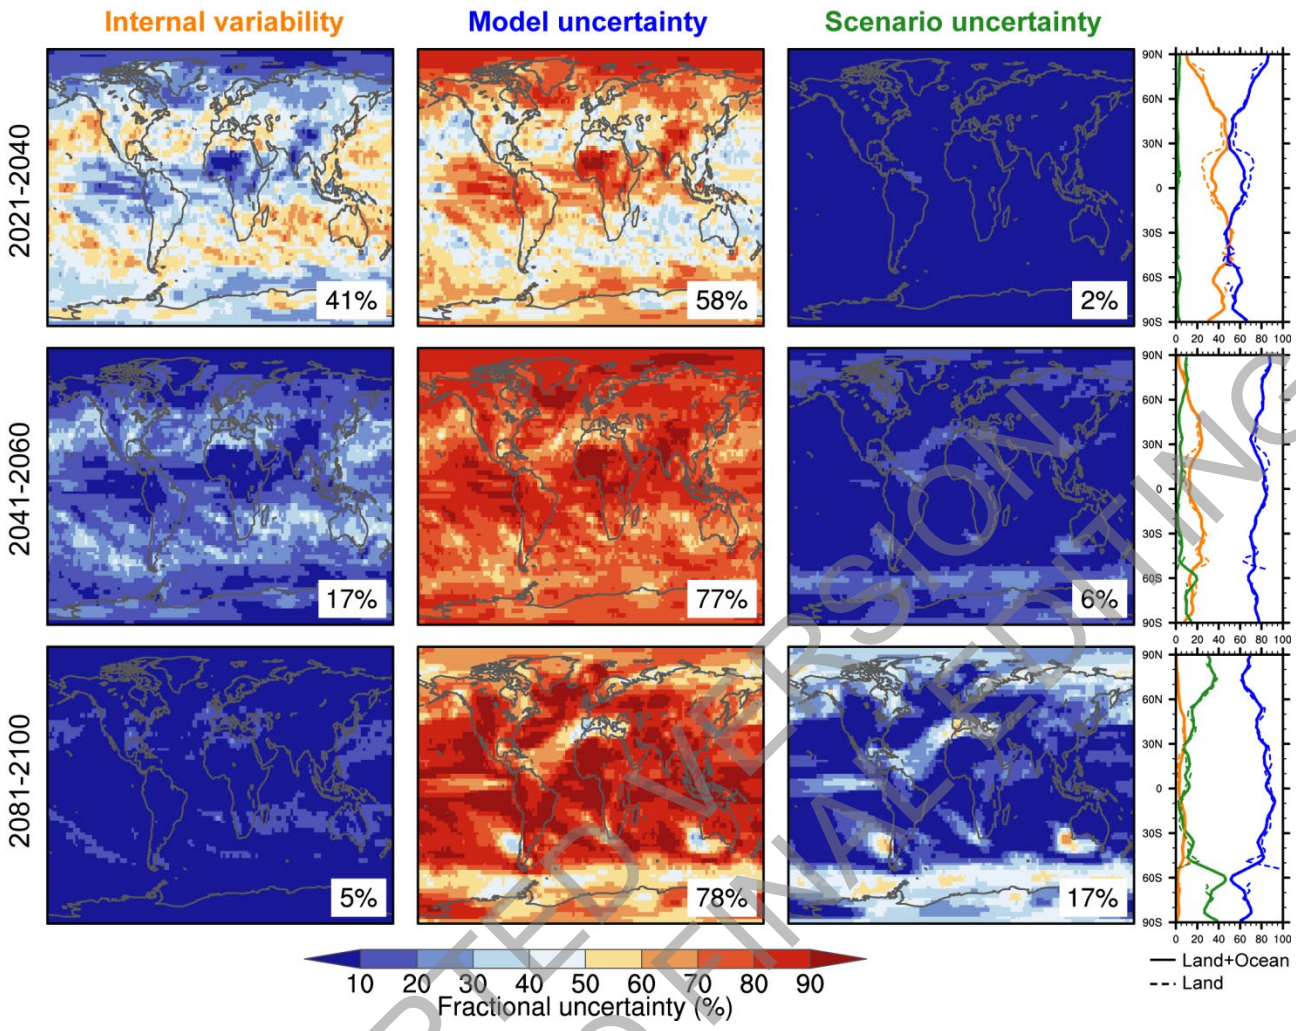

Figure 8.23: Geographical and zonal mean distribution of the percentage of variance explained by the three sources of uncertainty in CMIP6 projections of 20-year mean precipitation changes in 2021–2040 (top), 2041–2060 (middle) and 2081–2100 (bottom) relative to the 1995–2014 base period: internal climate variability (left), model response uncertainty (middle) and scenario uncertainty (right, considering four plausible concentration scenarios: SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5). Percentage numbers give the area-weighted global average value for each map. Right panels show the zonal mean fractions over both land and sea (solid lines) and over land only (dashed line). The figure was adapted from Fig.4a in (Lehner et al., 2020). The relative contributions of internal variability, models and emission scenarios to the total uncertainty depend on both region and time horizon. The scenario uncertainty is relatively low in near and mid-term time horizons while it increases in the long-term mostly over the high-latitudes. The model response uncertainty is the most influential factor across all time horizons. Internal variability also plays a key role in the near-term, especially in the subtropics. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

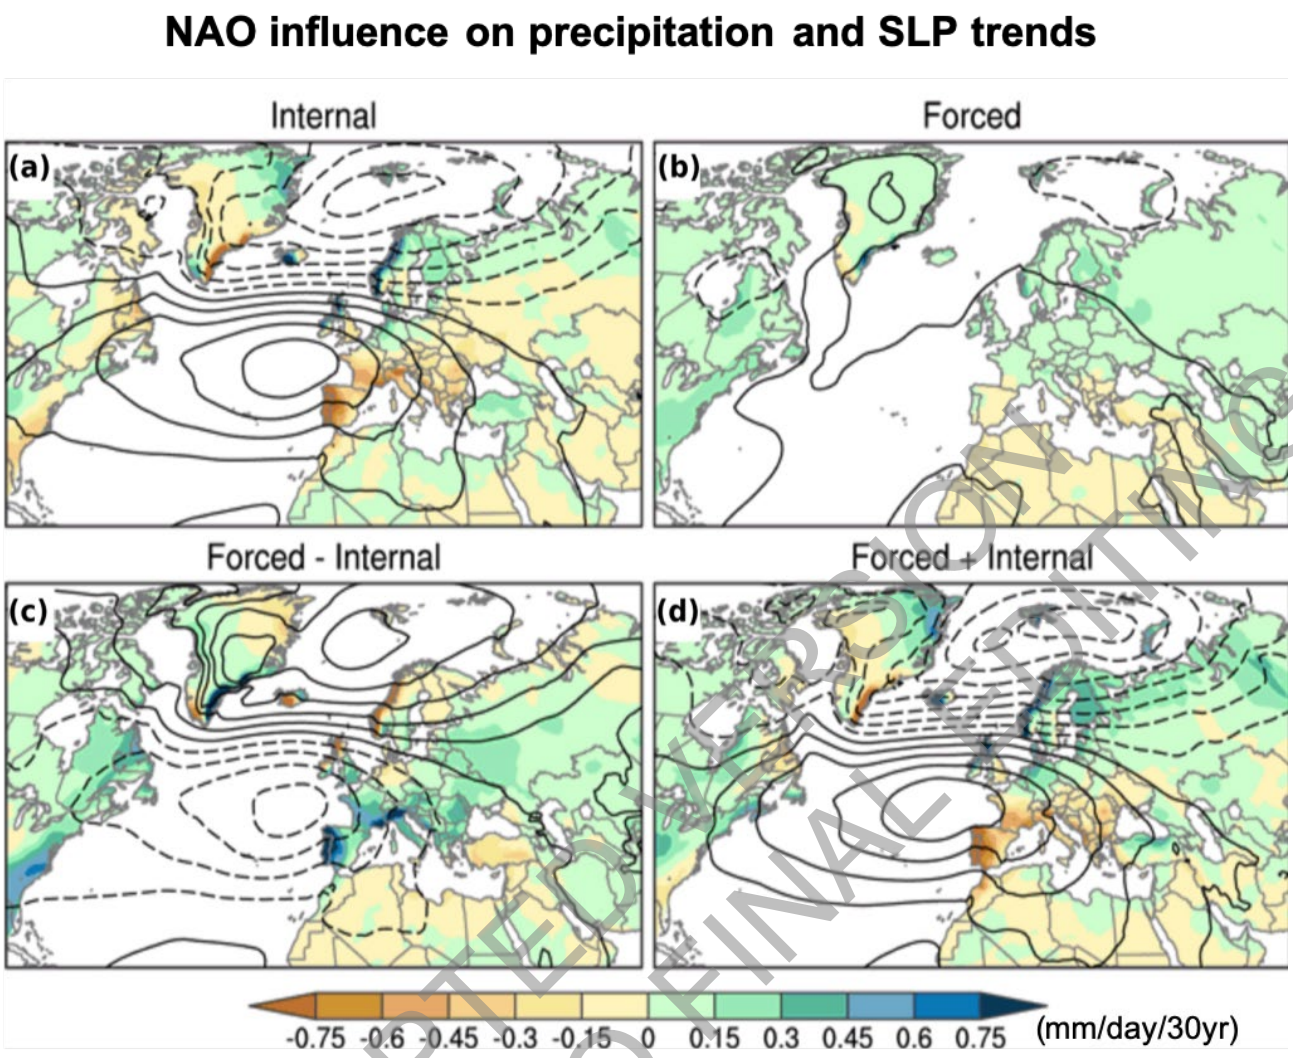
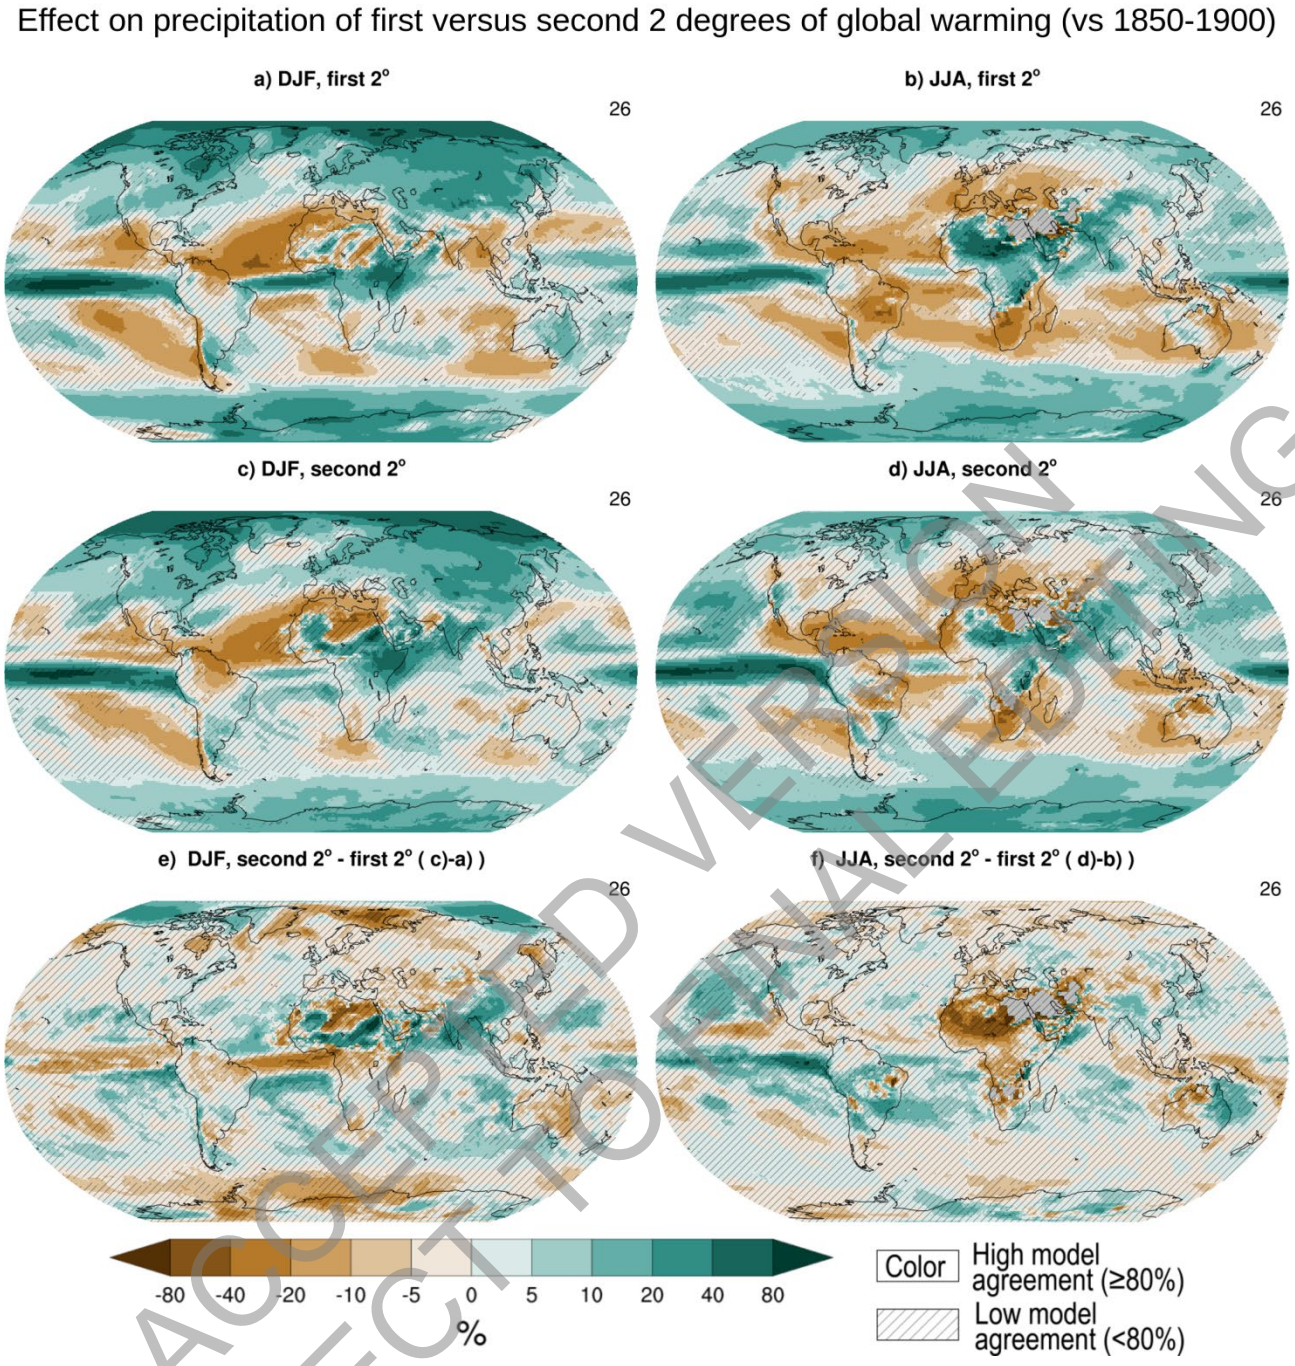
ACCEPTED VERSION SUBJECT TO FINAL EDITING





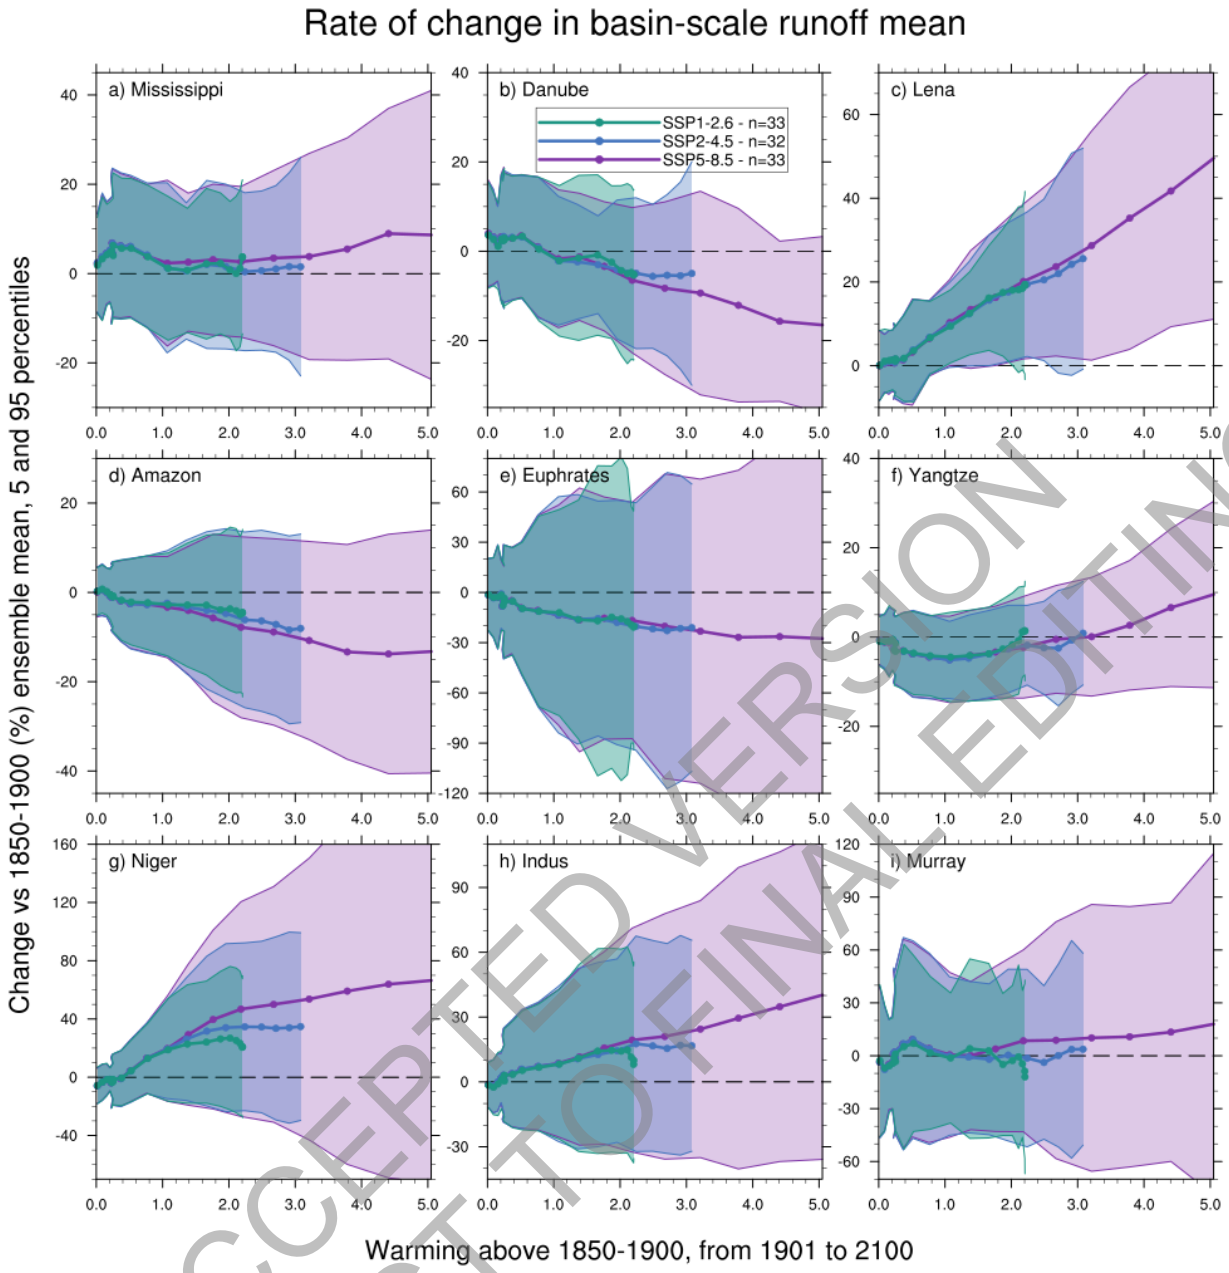


Figure 8.24: Impact of the North Atlantic Oscillation (NAO) on 2016–2045 climate trends. (a) Regressions of winter sea level pressure (SLP) and precipitation trends upon the normalized leading principal component (PC)of winter SLP trends in the CESM1 Large Ensemble, multiplied by two to correspond to a two standard deviation anomaly of the PC (as internal climate variability component); (b) CESM1 ensemble-mean winter SLP and precipitation trends (as forced climate variability component); (c) b – a (forced minus internal climate variability component); (d) b + a (forced plus internal climate variability component). Precipitation in color shading (mm/day per 30 years) and SLP in contours (interval = 1 hPa per 30 years with negative values dashed) (Adapted from Deser et al., 2017). Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

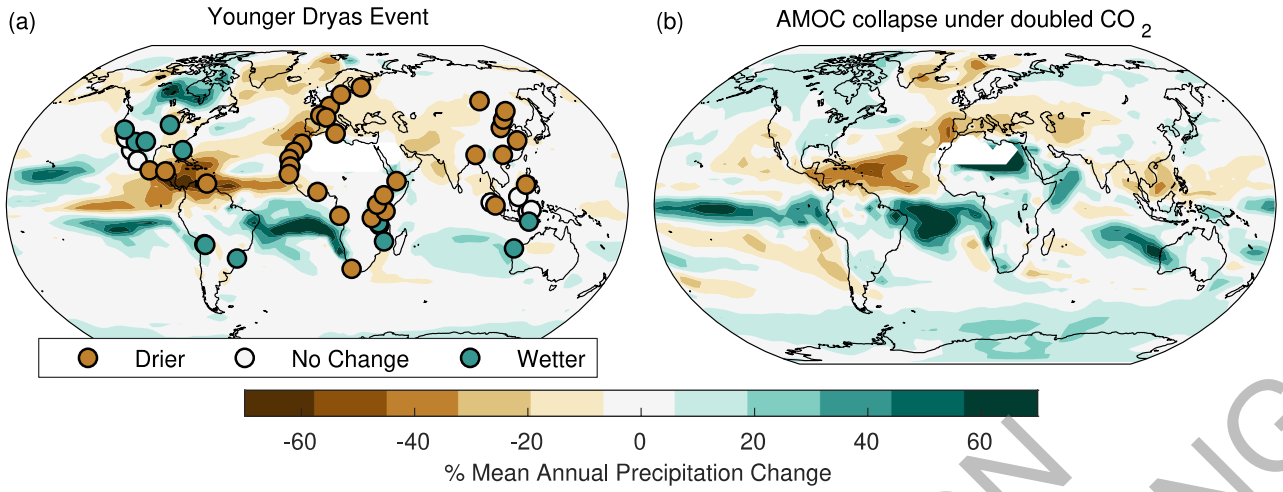
Figure 8.25: Effect of first versus second 2°C of global warming relative to the 1850-1900 base period on seasonal mean precipitation (mm/day). CMIP6 multi-model ensemble mean DJF (left panels) and JJA (right panels) precipitation difference for a,b) SSP5-8.5 at +2°C; c,d) SSP5-8.5 at +4°C minus SSP5-8.5 at +2°C (second 2°C warming); e,f) second minus first 2°C fast warming (c-a and d-b). Only models reaching the +4°C warming levels in SSP5-8.5 are considered. Differences are computed based on 21-yr time windows centered on the first year reaching or exceeding the selected global warming level using a 21-yr running mean global surface atmospheric temperature criterion. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Figure 8.26: Rate of change in basin-scale annual mean runoff with increasing global warming levels. Relative changes (%) in basin-averaged annual mean runoff estimated as multi-model ensemble median from a variable subset of CMIP6 models for each SSP over six major river basins: a) Mississipi, b) Danube, c) Lena, d) Amazon, e) Euphrates, f) Yangtze, g) Niger, h) Indus, i) Murray. The basin averages have been estimated after a first-order conservative remapping of the model outputs on the 0.5° by 0.5° river network of (Decharme et al., 2019). The shaded area indicates the 5-95% confidence interval of the ensemble values across all SSPs. Note that the y-axis range differs across basins and is particularly large for Niger and Murray (panels g and i). The number of models considered is specified for each scenario in the legend located inside panel b. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).



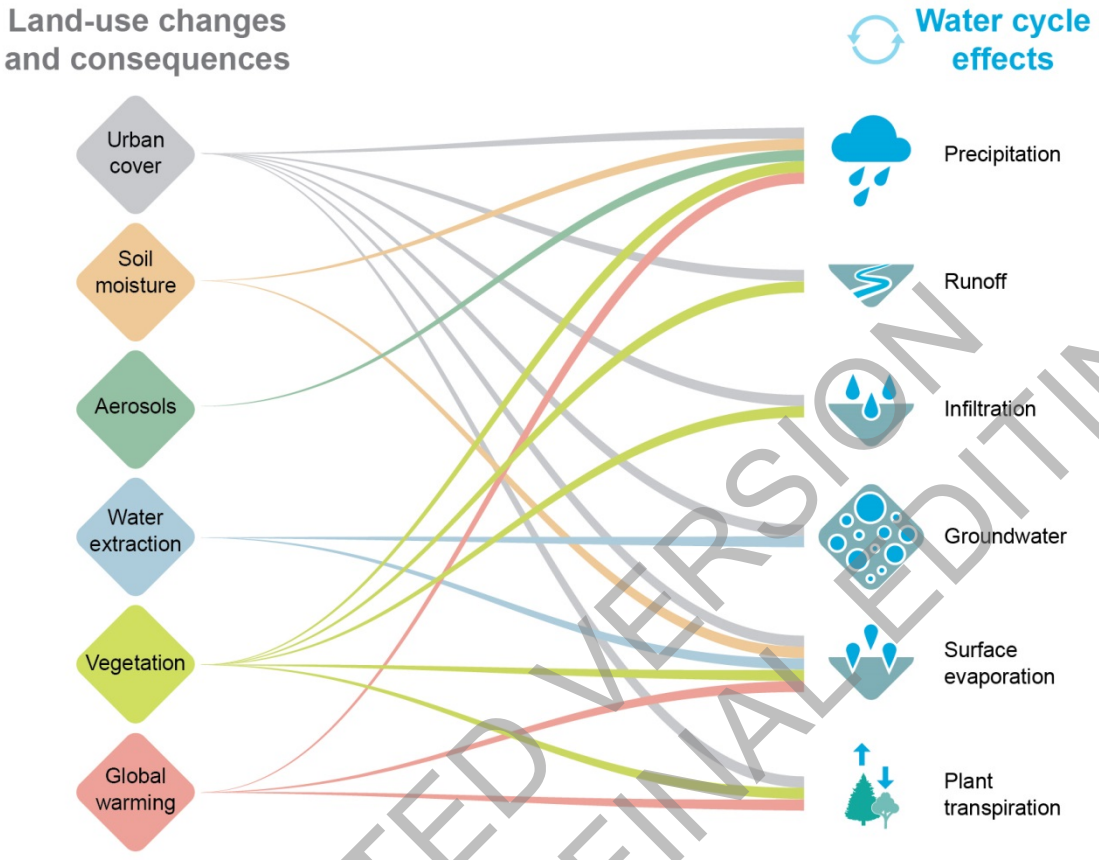


Figure 8.27: (a) Model simulation of precipitation response to the Younger Dryas event relative to the preceding warm Bølling-Allerød period (base colors, calculated as the difference between 12,600–11,700 yr BP and 14,500–12,900 BP from the TraCE paleoclimate simulation of Liu et al., (2009)), with paleoclimate proxy evidence superimposed on top (dots). (b) Model simulation of precipitation response to an abrupt collapse in AMOC under a doubling of 1990 CO_2 levels (after Liu et al., (2017)). Regions with rainfall rates below 20 mm/year are masked. Further details on data sources and processing are available in the chapter data table (Table 8.SM.1).

Chapter 9: Ocean, cryosphere and sea level change

Coordinating Lead Authors:
Baylor Fox-Kemper (United States of America), Helene T. Hewitt (United Kingdom), Cunde Xiao (China)

Lead Authors:
Guðfinna Aðalgeirsdóttir (Iceland), Sybren S. Drijfhout (The Netherlands), Tamsin L. Edwards (United Kingdom), Nicholas R. Golledge (New Zealand/United Kingdom), Mark Hemer (Australia), Robert E. Kopp (United States of America), Gerhard Krinner (France/Germany, France), Alan Mix (United States of America), Dirk Notz (Germany), Sophie Nowicki (United States of America/France, United States of America), Intan Suci Nurhati (Indonesia), Lucas Ruiz (Argentina), Jean-Baptiste Sallée (France), Aimee B. A. Slangen (The Netherlands), Yongqiang Yu (China)

Contributing Authors:
Cecile Agosta (France), Kyle Armour (United States of America), Mathias Aschwanden (Switzerland), Jonathan L. Bamber (United Kingdom), Sophie Berger (France/Belgium), Fábio Boeira Dias (Finland/Brazil), Jason E. Box (Denmark/USA), Eleanor J. Burke (United Kingdom), Kevin D. Burke (United States of America), Xavier Capet (France), John A. Church (Australia), Lee de Mora (United Kingdom), Chris Derksen (Canada), Catia M. Domingues (Australia, United Kingdom/Brazil), Jakob Dörr (Norway/Germany), Paul J. Durack (United States of America/Australia), Thomas L. Frölicher (Switzerland), Thian Y. Gan (Canada/Malaysia), Gregory G. Garner (United States of America), Sebastian Gerland (Norway/Germany), Heiko Goelzer (Norway/Germany), Natalya Gomez (Canada), Irina V. Gorodetskaya (Portugal/Belgium,Russian Federation), Jonathan M. Gregory (United Kingdom), Robert Hallberg (United States of America), F. Alexander Haumann (United States of America/Germany), Tim H. J. Hermans (The Netherlands), Emma M. Hill (Singapore/United States of America, United Kingdom), Regine Hock (United States of America, Norway/Germany), Stefan Hofer (Norway/Austria), Romain Hugonnet (France,Switzerland/France), Philippe Huybrechts (Belgium), Akm Saiful Islam (Bangladesh), Laura C. Jackson (United Kingdom), Nicolas C. Jourdain (France), Andreas Kääb (Norway/Germany), Nicole S. Khan (Hong Kong,China/USA), Shfaqat Abbas Khan (Denmark), Matthew Kirwan (United States of America), James Kossin (United States of America), Anders Levermann (Germany), Sophie Lewis (Australia), Shiyin Liu (China), Daniel Lowry (New Zealand/United States of America), Marta Marcos (Spain), Ben Marzeion (Germany), Matthew Menary (France/United Kingdom), Sebastian H. Mernild (Norway, Denmark/Norway), Philip Orton (United States of America), Matthew D. Palmer (United Kingdom), Frank Pattyn (Belgium), Brodie Pearson (United States of America/United Kingdom), Cécile Pellet (Switzerland), Chris Perry (United Kingdom), Mark D. Executive Summary

This chapter assesses past and projected changes in the ocean, cryosphere and sea level using paleo-reconstructions, instrumental observations and model simulations. In the following summary, we update and expand the related assessments from the IPCC Fifth Assessment Report (AR5), the Special Report on Global Warming of 1.5ºC (SR1.5) and the Special Report on Ocean and Cryosphere in a Changing Climate (SROCC). Major advances in this chapter since the SROCC include the synthesis of extended and new observations, which allows for improved assessment of past change, processes and budgets for the last century, and the use of a hierarchy of models and emulators, which provide improved projections and uncertainty estimates of future change. In addition, the systematic use of model emulators makes our projections of ocean heat content, land-ice loss and sea level rise fully consistent both with each other and with the assessed equilibrium climate sensitivity and projections of global surface air temperature across the entire report. In this executive summary, uncertainty ranges are reported as *very likely* ranges and expressed by square brackets, unless otherwise noted.

Ocean Heat and Salinity

At the ocean surface, temperature has on average increased by 0.88 [0.68–1.01] °C from 1850-1900 to 2011-2020, with 0.60 [0.44–0.74] °C of this warming having occurred since 1980. The ocean surface temperature is projected to increase from 1995–2014 to 2081–2100 on average by 0.86 [0.43–1.47, *likely* range] °C in SSP1-2.6 and by 2.89 [2.01–4.07, *likely* range] °C in SSP5-8.5. Since the 1950s, the fastest surface warming has occurred in the Indian Ocean and in Western Boundary Currents, while ocean circulation has caused slow warming or surface cooling in the Southern Ocean, equatorial Pacific, North Atlantic, and coastal upwelling systems (*very high confidence*). At least 83% of the ocean surface will *very likely* warm over the 21st century in all SSP scenarios. {2.3.3, 9.2.1}

The heat content of the global ocean has increased since at least 1970 and will continue to increase over the 21st century (*virtually certain*). The associated warming will *likely* continue until at least 2300 even for low-emission scenarios because of the slow circulation of the deep ocean. Ocean heat content has increased from 1971 to 2018 by [0.28–0.55] yottajoules and will *likely* increase until 2100 by 2 to 4 times that amount under SSP1-2.6 and 4 to 8 times that amount under SSP5-8.5. The long time scale also implies that the amount of deep-ocean warming will only become scenario-dependent after about 2040 and that the warming is irreversible over centuries to millennia (*medium confidence*). On annual to decadal time scales, the redistribution of heat by the ocean circulation dominates spatial patterns of temperature change (*high confidence*). At longer time scales, the spatial patterns are dominated by additional heat primarily stored in water-masses formed in the Southern Ocean, and by weaker warming in the North Atlantic where heat redistribution caused by changing circulation counteracts the additional heat input through the surface (*high confidence*). {9.2.2, 9.2.4, 9.6.1, Cross-Chapter Box 9.1}

Marine heatwaves – sustained periods of anomalously high near-surface temperatures that can lead to severe and persistent impacts on marine ecosystems – have become more frequent over the 20th century (*high confidence*). Since the 1980s, they have approximately doubled in frequency (*high confidence*) and have become more intense and longer (*medium confidence*). This trend will continue, with marine heatwaves at global scale becoming 4 [2–9, *likely* range] times more frequent in 2081–2100 compared to 1995–2014 under SSP1-2.6, and 8 [3–15, *likely* range] times more frequent under SSP5-8.5. The largest changes will occur in the tropical ocean and the Arctic (*medium confidence*). {Box 9.2}

The upper ocean has become more stably stratified since at least 1970 over the vast majority of the globe (*virtually certain*), primarily due to surface-intensified warming and high-latitude surface freshening (*very high confidence*). Changes in ocean stability affect vertical exchanges of surface waters with the deep ocean and large-scale ocean circulation. Based on recent refined analyses of the available

ACCEPTED VERSION SUBJECT TO FINAL EDITING

observations, the global 0–200 m stratification is now assessed to have increased about twice as much as reported by the SROCC, with a 4.9 ± 1.5% increase from 1970 to 2018 (*high confidence*) and even higher increases at the base of the surface mixed layer. Upper-ocean stratification will continue to increase throughout the 21st century (*virtually certain*). {9.2.1}

Ocean Circulation

The Atlantic Meridional Overturning Circulation (AMOC) will *very likely* decline over the 21st century for all SSP scenarios. There is *medium confidence* that the decline will not involve an abrupt collapse before 2100. For the 20th century, there is *low confidence* in reconstructed and modelled AMOC changes because of their *low agreement* in quantitative trends. The *low confidence* also arises from new observations that indicate missing key processes in both models and measurements used for formulating proxies and from new evaluations of modelled AMOC variability. This results in *low confidence* in quantitative projections of AMOC decline in the 21st century, despite the *high confidence* in the future decline as a qualitative feature based on process understanding. {9.2.3}

Southern Ocean circulation and associated temperature changes in Antarctic ice-shelf cavities are sensitive to changes in wind patterns and increased ice-shelf melt (*high confidence*). However, limitations in understanding feedback mechanisms involving the ocean, atmosphere and cryosphere, which are not fully represented in the current generation of climate models, generally limit our confidence in future projections of the Southern Ocean and of its forcing on Antarctic sea ice and ice shelves. {9.2.3, 9.3.2, 9.4.2}

Many ocean currents will change in the 21st century as a response to changes in wind stress associated with anthropogenic warming (*high confidence*). Western boundary currents have shifted poleward since 1993 (*medium confidence*), consistent with a poleward shift of the subtropical gyres. Of the four eastern boundary upwelling systems, only the California current system has experienced some large-scale upwelling-favourable wind intensification since the 1980s (*medium confidence*). In the 21st century, consistent with projected changes in the surface winds, the East Australian Current Extension and Agulhas Current Extension will intensify, while the Gulf Stream and Indonesian Throughflow will weaken (*medium confidence*). Eastern boundary upwelling systems will change, with a dipole spatial pattern within each system of reduction at low latitude and enhancement at high latitude (*high confidence*). {9.2.1, 9.2.3}

Sea Ice

The Arctic Ocean will *likely* become practically sea ice–free[1] during the seasonal sea ice minimum for the first time before 2050 in all considered SSP scenarios. There is no tipping point for this loss of Arctic summer sea ice (*high confidence*). The practically ice-free state is projected to occur more often with higher greenhouse gas concentrations and will become the new normal for high-emission scenarios by the end of this century (*high confidence*). Based on observational evidence, Coupled Model Intercomparison Project Phase 6 (CMIP6) models and conceptual understanding, the substantial satellite-observed decrease of Arctic sea ice area over the period 1979–2019 is well described as a linear function of global mean surface temperature, and thus of cumulative anthropogenic CO_2 emissions, with superimposed internal variability (*high confidence*). According to both process understanding and CMIP6 simulations, a practically sea ice–free state will *likely* be observed in some years before additional (post-2020) cumulative anthropogenic CO_2 emissions reach 1000 $GtCO_2$. {4.3.2, 9.3.1}

[1] sea ice area below 1 million km^2

ACCEPTED VERSION SUBJECT TO FINAL EDITING

For Antarctic sea ice, regionally opposing trends and large interannual variability result in no significant trend in satellite-observed sea ice area from 1979 to 2020 in both winter and summer (*high confidence*). The regionally opposing trends result primarily from changing regional wind forcing (*medium confidence*). There is *low confidence* in model simulations of past and future Antarctic sea ice evolution due to deficiencies of process representation, in particular at the regional level. {2.3.2, 9.2.3, 9.3.2}

Ice Sheets

The Greenland Ice Sheet has lost 4890 [4140–5640] Gt mass over the period 1992–2020, equivalent to 13.5 [11.4–15.6] mm global mean sea level rise. The mass-loss rate was on average 39 [–3 to 80] Gt yr^{-1} over the period 1992–1999, 175 [131 to 220] Gt yr^{-1} over the period 2000–2009 and 243 [197 to 290] Gt yr^{-1} over the period 2010–2019. This mass loss is driven by both discharge and surface melt, with the latter increasingly becoming the dominating component of mass loss with high interannual variability in the last decade (*high confidence*). The largest mass losses occurred in the Northwest and the Southeast of Greenland (*high confidence*). {2.3.2, 9.4.1}

The Antarctic Ice Sheet has lost 2670 [1800–3540] Gt mass over the period 1992–2020, equivalent to 7.4 [5.0–9.8] mm global mean sea level rise. The mass-loss rate was on average 49 [–2 to 100] Gt yr^{-1} over the period 1992–1999, 70 [22 to 119] Gt yr^{-1} over the period 2000–2009 and 148 [94 to 202] Gt yr^{-1} over the period 2010–2019. Mass losses from West Antarctic outlet glaciers outpaced mass gain from increased snow accumulation on the continent and dominated the ice sheet mass losses since 1992 (*very high confidence*). These mass losses from the West Antarctic outlet glaciers were mainly induced by ice shelf basal melt (*high confidence*) and locally by ice shelf disintegration preceded by strong surface melt (*high confidence*). Parts of the East Antarctic Ice Sheet have lost mass in the last two decades (*high confidence*). {2.3.2, 9.4.2, Atlas.11.1}

Both the Greenland Ice Sheet (*virtually certain*) and the Antarctic Ice Sheet (*likely*) will continue to lose mass throughout this century under all considered SSP scenarios. The related contribution to global mean sea level rise until 2100 from the Greenland Ice Sheet will *likely* be 0.01–0.10 m under SSP 1-2.6, 0.04–0.13 m under SSP2-4.5 and 0.09–0.18 m under SSP5-8.5, while the Antarctic Ice Sheet will *likely* contribute 0.03–0.27 m under SSP1-2.6, 0.03–0.29 m under SSP2-4.5 and 0.03–0.34 m under SSP5-8.5. The loss of ice from Greenland will become increasingly dominated by surface melt, as marine margins retreat and the ocean-forced dynamic response of ice-sheet margins diminishes (*high confidence*). In the Antarctic, dynamic losses driven by ocean warming and ice shelf disintegration will *likely* continue to outpace increasing snowfall this century (*medium confidence*). Beyond 2100, total mass loss from both ice sheets will be greater under high-emission scenarios than under low-emission scenarios (*high confidence*). The assessed *likely* ranges consider those ice-sheet processes in whose representation in current models we have at least *medium confidence*, including surface mass balance and grounding-line retreat in the absence of instabilities. Under high-emission scenarios, poorly understood processes related to Marine Ice Sheet Instability and Marine Ice Cliff Instability, characterized by deep uncertainty, have the potential to strongly increase Antarctic mass loss on century to multi-century time scales. {9.4.1, 9.4.2, 9.6.3, Box 9.3, Box 9.4}

Glaciers

Glaciers lost 6200 [4600–7800] Gt of mass (17.1 [12.7–21.5] mm global mean sea level equivalent) over the period 1993 to 2019 and will continue losing mass under all SSP scenarios (*very high confidence*). During the decade 2010 to 2019, glaciers lost more mass than in any other decade since the beginning of the observational record (*very high confidence*). For all regions with long-term observations, glacier mass in the decade 2010 to 2019 is the smallest since at least the beginning of the 20th century (*medium confidence*). Because of their lagged response, glaciers will continue to lose mass at least for several decades even if global temperature is stabilized (*very high confidence*). Glaciers will lose 29,000 [9,000–49,000] Gt

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and 58,000 [28,000–88,000] Gt over the period 2015–2100 for RCP2.6 and RCP8.5, respectively (*medium confidence*), which represents 18 [5–31] % and 36 [16–56] % of their early-21st-century mass, respectively. {2.3.2, 9.5.1, 9.6.1, 9.6.3, 12.4}

Permafrost

Increases in permafrost temperature have been observed over the past three to four decades throughout the permafrost regions (*high confidence*), and further global warming will lead to near-surface permafrost volume loss (*high confidence*). Complete permafrost thaw in recent decades is a common phenomenon in discontinuous and sporadic permafrost regions (*medium confidence*). Permafrost warmed globally by 0.29 [0.17–0.41, *likely* range] °C between 2007 and 2016 (*medium confidence*). An increase in the active layer thickness is a pan-Arctic phenomenon (*medium confidence*), subject to strong heterogeneity in surface conditions. The volume of perennially frozen soil within the upper 3 m of the ground will decrease by about 25% per 1°C of global surface air temperature change (up to 4°C above pre-industrial temperature) (*medium confidence*). {9.5.2}

Snow

Northern Hemisphere spring snow cover extent has been decreasing since 1978 (*very high confidence*), and there is *high confidence* that this trend extends back to 1950. Further decrease of Northern Hemisphere seasonal snow cover extent is *virtually certain* under further global warming. The observed sensitivity of Northern Hemisphere snow cover extent to Northern Hemisphere land surface air temperature for 1981–2010 is –1.9 [–2.8 to –1.0, *likely* range] million km^2 per 1°C throughout the snow season. It is *virtually certain* that Northern Hemisphere snow cover extent will continue to decrease as global climate continues to warm, and process understanding strongly suggests that this also applies to Southern Hemisphere seasonal snow cover (*high confidence*). Northern Hemisphere spring snow cover extent will decrease by about 8% per 1°C of global surface air temperature change (up to 4°C above pre-industrial temperature) (*medium confidence*). {9.5.3}

Sea Level

Global mean sea level (GMSL) rose faster in the 20th century than in any prior century over the last three millennia (*high confidence*), with a 0.20 [0.15–0.25] m rise over the period 1901 to 2018 (*high confidence*). GMSL rise has accelerated since the late 1960s, with an average rate of 2.3 [1.6–3.1] mm yr^{-1} over the period 1971–2018 increasing to 3.7 [3.2–4.2] mm yr^{-1} over the period 2006–2018 (*high confidence*). New observation-based estimates published since SROCC lead to an assessed sea level rise over the period 1901 to 2018 that is consistent with the sum of individual components. While ocean thermal expansion (38%) and mass loss from glaciers (41%) dominate the total change from 1901 to 2018, ice sheet mass loss has increased and accounts for about 35% of the sea level increase during the period 2006–2018 (*high confidence*). {2.3.3, 9.6.1, 9.6.2, Cross-Chapter Box 9.1, Box 7.2}

At the basin scale, sea levels rose fastest in the Western Pacific and slowest in the Eastern Pacific over the period 1993–2018 (*medium confidence*). Regional differences in sea level arise from ocean dynamics; changes in Earth gravity, rotation and deformation due to land-ice and land-water changes; and vertical land motion. Temporal variability in ocean dynamics dominates regional patterns on annual to decadal time scales (*high confidence*). The anthropogenic signal in regional sea level change will emerge in most regions by 2100 (*medium confidence*). {9.2.4, 9.6.1}

Regional sea level change has been the main driver of changes in extreme still water levels across the quasi-global tide gauge network over the 20th century (*high confidence*) and will be the main driver of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

a substantial increase in the frequency of extreme still water levels over the next century (*medium confidence*). Observations show that high tide flooding events that occurred five times per year during the period 1960–1980 occurred on average more than eight times per year during the period 1995–2014 (*high confidence*). Under the assumption that other contributors to extreme sea levels remain constant (e.g., stationary tides, storm-surge, and wave climate), extreme sea levels that occurred once per century in the recent past will occur annually or more frequently at about 19–31% of tide gauges by 2050 and at about 60% (SSP1-2.6) to 82% (SSP5-8.5) of tide gauges by 2100 (*medium confidence*). In total, such extreme sea levels will occur about 20 to 30 times more frequently by 2050 and 160 to 530 times more frequently by 2100 compared to the recent past, as inferred from the median amplification factors for SSP1-2.6, SSP2-4.5, and SSP5-8.5 (*medium confidence*). Over the 21st century, the majority of coastal locations will experience a median projected regional sea level rise within +/- 20% of the median projected GMSL change (*medium confidence*). {9.6.4}

It is *virtually certain* that global mean sea level will continue to rise through 2100, because all assessed contributors to global mean sea level are *likely* to *virtually certain* to continue contributing throughout this century. Considering only processes for which projections can be made with at least *medium confidence*, relative to the period 1995–2014 GMSL will rise by 2050 between 0.18 [0.15–0.23, *likely* range] m (SSP1-1.9) and 0.23 [0.20–0.30, *likely* range] m (SSP5-8.5), and by 2100 between 0.38 [0.28–0.55, *likely* range] m (SSP1-1.9) and 0.77 [0.63–1.02, *likely* range] m (SSP5-8.5). This GMSL rise is primarily caused by thermal expansion and mass loss from glaciers and ice sheets, with minor contributions from changes in land-water storage. These *likely* range projections do not include those ice-sheet-related processes that are characterized by deep uncertainty. {9.6.3}

Higher amounts of GMSL rise before 2100 could be caused by earlier-than-projected disintegration of marine ice shelves, the abrupt, widespread onset of Marine Ice Sheet Instability and Marine Ice Cliff Instability around Antarctica, and faster-than-projected changes in the surface mass balance and discharge from Greenland. These processes are characterised by deep uncertainty arising from limited process understanding, limited availability of evaluation data, uncertainties in their external forcing and high sensitivity to uncertain boundary conditions and parameters. In a low-likelihood, high-impact storyline, under high emissions such processes could in combination contribute more than one additional meter of sea level rise by 2100. {9.6.3, Box 9.4}

Beyond 2100, GMSL will continue to rise for centuries due to continuing deep ocean heat uptake and mass loss of the Greenland and Antarctic Ice Sheets, and will remain elevated for thousands of years (*high confidence*). Considering only processes for which projections can be made with at least *medium confidence* and assuming no increase in ice-mass flux after 2100, relative to the period 1995–2014, by 2150, GMSL will rise between 0.6 [0.4–0.9, *likely* range] m (SSP1-1.9) and 1.4 [1.0–1.9, *likely* range] m (SSP5-8.5). By 2300, GMSL will rise between 0.3 m and 3.1 m under SSP1-2.6, between 1.7 m and 6.8 m under SSP5-8.5 in the absence of Marine Ice Cliff Instability, and by up to 16 m under SSP5-8.5 considering Marine Ice Cliff Instability (*low confidence*). {9.6.3}

Cryospheric Changes and Sea Level Rise at Specific Levels of Global Warming

At sustained warming levels between 1.5°C and 2°C, the Arctic Ocean will become practically sea ice–free in September in some years (*medium confidence*); the ice sheets will continue to lose mass (*high confidence*), but will not fully disintegrate on time scales of multiple centuries (*medium confidence*); there is *limited evidence* that the Greenland and West Antarctic Ice Sheets will be lost almost completely and irreversibly over multiple millennia; about 50–60% of current glacier mass excluding the two ice sheets and the glaciers peripheral to the Antarctic Ice Sheet will remain, predominantly in the polar regions (*low confidence*); Northern hemisphere spring snow cover extent will decrease by up to 20% relative to 1995–2014 (*medium confidence*); the permafrost volume in the top 3 m will decrease by up to 50% relative to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

1995–2014 (*medium confidence*). Committed GMSL rise over 2000 years will be about 2-6 m with 2°C of peak warming (*medium agreement, limited evidence*). {9.3.1, 9.4.1, 9.4.2, 9.5.1, 9.5.2, 9.5.3, 9.6.3}

At sustained warming levels between 2°C and 3°C, the Arctic Ocean will be practically sea ice–free throughout September in most years (*medium confidence*); there is *limited evidence* that the Greenland and West Antarctic Ice Sheets will be lost almost completely and irreversibly over multiple millennia; both the probability of their complete loss and the rate of mass loss will increase with higher temperatures (*high confidence*); about 50–60% of current glacier mass outside Antarctica will be lost (*low confidence*); Northern hemisphere spring snow cover extent will decrease by up to 30% relative to 1995–2014 (*medium confidence*); permafrost volume in the top 3 m will decrease by up to 75% relative to 1995–2014 (*medium confidence*). Committed GMSL rise over 2000 years will be about 4-10 m with 3°C of peak warming (*medium agreement, limited evidence*). {9.3.1, 9.4.1, 9.4.2, 9.5.1, 9.5.2, 9.5.3, 9.6.3}

At sustained warming levels between 3°C and 5°C, the Arctic Ocean will become practically sea ice–free throughout several months in most years (*high confidence*); near-complete loss of the Greenland Ice Sheet and complete loss of the West Antarctic Ice Sheet will occur irreversibly over multiple millennia (*medium confidence*); substantial parts or all of Wilkes Subglacial Basin in East Antarctica will be lost over multiple millennia (*low confidence*); 60–75% of current glacier mass outside Antarctica will disappear (*low confidence*); nearly all glacier mass in low latitudes, Central Europe, Caucasus, Western Canada and USA, North Asia, Scandinavia and New Zealand will *likely* disappear; Northern Hemisphere spring snow cover extent will decrease by up to 50% relative to 1995–2014 (*medium confidence*); permafrost volume in the top 3 m will decrease by up to 90% compared to 1995–2014 (*medium confidence*). Committed GMSL rise over 2000 years will be about 12–16 m with 4°C of peak warming and 19–22 m with 5°C of peak warming (*medium agreement, limited evidence*). {9.3.1, 9.4.1, 9.4.2, 9.5.1, 9.5.2, 9.5.3, 9.6.3}

9.1 Introduction

This chapter provides a holistic assessment of the physical processes underlying global and regional changes in the ocean, cryosphere and sea level, as well as improved understanding of observed, attributed and projected future changes since the AR5 and the SROCC (see outline in Figure 9.1). The ocean and cryosphere (defined as the frozen components of the Earth system such as sea ice, ice sheets, glaciers, permafrost and snow) exchange heat and freshwater with the atmosphere and each other (Figure 9.2). In a warming climate, the combined effects of thermal expansion of seawater and melting of the terrestrial cryosphere result in global mean sea-level rise (Box 9.1).

[START FIGURE 9.1 HERE]

Figure 9.1: Visual guide to chapter 9 with relevant chapter numbers indicated in red.

[END FIGURE 9.1 HERE]

Ocean acidification and deoxygenation are covered in Chapter 5 and regional changes to the ocean and cryosphere are covered in Chapter 12 and the Atlas. Ecosystem range shifts and climate risk for marine biodiversity associated with ocean change are assessed in AR6 Working Group II. The notion of "climate velocity" often used in impact studies, which is defined as the speed and direction at which a climate variable moves across a corresponding spatial field is underpinned by the assessment of changes in the physical characteristics of the ocean provided in this chapter.

There are two major advances of this chapter compared with the AR5 and the SROCC facilitated by community efforts. The first is the temporal and spatial increase in observations of both the ocean and the cryosphere (Section 1.5.1.1). In particular, extended observations have allowed improved assessment of past change and closure of both the energy and sea-level budget in a consistent way (Cross-Chapter Box 9.1) and the sea level budget for the last century (Section 9.6.1.1). Higher resolution observations have revealed the details of the Atlantic meridional overturning circulation (Section 9.2.3.1) and globally resolved glacier changes for the first time (Section 9.5.1.1). Improved methodology has resulted in a doubling of the assessed level of observed increase in global ocean 0–200 m stratification compared to the SROCC assessment (Section 9.2.1.3).

The second advance is the use of a hierarchy of models and emulators to update projections of oceanic, cryospheric and sea-level change arising from CMIP6 and related projects (Section 1.5.4.3; Table 1.3, Annex II).[2] CMIP6 included an ice sheet modelling intercomparison for the first time. Particular modelling advances relevant to this chapter are the increase in ocean resolution in the HighResMIP and OMIP2 experiments (Section 1.5.3.1; Section 9.2), projections of future glacier (GlacierMIP) and ice sheet (ISMIP6 and LARMIP-2) response from multi-model studies (Sections 9.5.1, 9.4; Box 9.3), and new methods to synthesize ocean and cryosphere models into sea level projections for all SSPs (Section 1.6.1; Cross-Chapter Box 1.4; Sections 9.4.1.3, 9.4.2.5, 9.6.3) and warming levels (Sections 9.6.3; 1.6.2; Cross-Chapter Box 11.1). In particular, sea level projections and the individual contributions (Section 9.6.3.3) are consistent with equilibrium climate sensitivity and surface temperature assessments across this report (Box 4.1, Cross-Chapter Box 7.1).

There are other advances in scientific understanding. In the cryosphere, this chapter assesses how fast-responding elements (sea ice, permafrost and snow (Sections 9.3 9.5.2; 9.5.3) track warming levels across observations and projections independent of scenario, process understanding of uncertainty in Antarctic ice

[2] In particular, this range of tools leads to advance in evaluation of confidence in projections. When CMIP6 models are used without additional evidence, the 5-95% confidence range of projections is assigned to a *likely* range to acknowledge that there are uncertainty sources not reflected by model spread, consistent with Chapter 4.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

sheet projections (Section 9.4.2; Box 9.4) and new insight into thresholds for Arctic sea ice (Section 9.3.1.1) and Greenland and West Antarctic ice sheets (Section 9.4.1.4; 9.4.2.6). In the ocean, process understanding of ocean heat uptake (Section 9.2.2.1; Cross-chapter Box 5.3) and observed changes in ocean stratification (Section 9.2.1.3) have implications for ocean biogeochemistry are also important.

[START FIGURE 9.2 HERE]

Figure 9.2: Components of ocean, cryosphere and sea level assessed in this chapter. (a) Schematic of processes (mCDW=modified Circumpolar Deep Water, GIA=Glacial Isostatic Adjustment). White arrows indicate ocean circulation. Pinning points indicate where the grounding line is most stable and ice sheet retreat will slow. (b) Geographic distribution of ocean and cryosphere components (numbers indicate (RGI Consortium, 2017) glacierized regions, see Figures 9.20 and 9.21 for labels). Sea ice shaded to indicate the annual mean concentration. Green ocean colours indicate larger surface current speed. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.2 HERE]

[START BOX 9.1 HERE]

BOX 9.1: Key processes driving sea level change

Sea-level change arises from processes acting on a range of spatial and temporal scales, in the ocean, cryosphere, solid Earth, atmosphere and on land (Figure 9.2). ***Relative sea-level change*** is the change in local mean sea surface height relative to the sea floor, as measured by instruments that are fixed to the Earth's surface (e.g., tide gauges). This reference frame is used when considering coastal impacts, hazards and adaptation needs. In contrast, ***geocentric sea-level change*** is the change in local mean sea surface height with respect to the terrestrial reference frame and is the sea-level change observed with instruments from space. This box provides a brief summary of sea-level processes using standard terminology (Gregory et al., 2019).

Global processes

Global mean sea-level change (Sections 9.6, 2.3.3.3) is the change in volume of the ocean divided by the ocean surface area. It is the sum of changes in ocean density (*global mean thermosteric sea-level change*) and changes in the ocean mass as a result of changes in the cryosphere or land water storage (*barystatic sea-level change*).

Steric sea-level change is caused by changes in the ocean density and is composed of *thermosteric sea-level change* and *halosteric sea-level change*. ***Thermosteric sea-level change*** (also referred to as *thermal expansion*) occurs as a result of changes in ocean temperature: increasing temperature reduces ocean density and increases the volume per unit of mass. ***Halosteric sea-level change*** occurs as a result of salinity variations: higher salinity leads to higher density and decreases the volume per unit of mass. Although both processes can be relevant on regional to local scales, thermosteric changes contribute to global mean sea-level change, whereas global mean halosteric change is negligible (Gregory et al., 2019). There is *high confidence* in the understanding of processes causing thermosteric sea-level change (Section 9.2.4.1).

The Greenland and Antarctic ice sheets are the largest reservoirs of frozen freshwater and therefore potentially the largest contributors to sea-level rise. Fluctuations in ice sheet volume arise from the imbalance between accumulation (either at the ice sheet surface or on the underside of ice shelves) and loss from sublimation, surface and basal melting, and iceberg calving. Ice sheets discharge the majority of their mass through marine-terminating ice streams that are in some cases buttressed by floating ice shelves. Changes in the thickness and extent of the ice shelves due to melt from below, calving, or disintegration, as a result of surface meltwater penetrating crevasses, can affect the flow of the inland ice streams. There is *medium confidence* in ice sheet processes but *low confidence* in their forcing (ocean changes and ice shelf

ACCEPTED VERSION SUBJECT TO FINAL EDITING

collapse) and in instability processes (Sections 9.4.1, 9.4.2).[3]

Glaciers contribute to sea-level change via an imbalance between mass gain and mass loss processes, which leads to adjustments in the glacier geometry over an extended period of time, called the response time. The response time may range from a few years to a few hundred years. The glacial meltwater does not all flow immediately into the ocean: it can refreeze, feed rivers (where it may be extracted for domestic use), evaporate, or be stored in (proglacial) lakes or closed basins. There is *medium* to *high confidence* in the understanding of processes leading to sea level contributions from glaciers (Section 9.5.1).

Land water storage includes surface water, soil moisture, groundwater storage and snow, but excludes water stored in glaciers and ice sheets. Changes in land water storage can be caused either by direct human intervention in the water cycle (e.g., storage of water in reservoirs by building dams in rivers, groundwater extraction for consumption and irrigation, or deforestation) or by climate variations (e.g., changes in the amount of water in internally drained lakes and wetlands, the canopy, the soil, the permafrost and the snowpack). Land water storage changes caused by climate variations may be indirectly affected by anthropogenic influences. It is difficult to assign a single confidence level to land water storage as understanding can vary from *low confidence* in groundwater recharge processes to *high confidence* in water storage via snowpack changes (Sections 8.2.3, 8.3.1.7).

Regional and local processes

Ocean dynamic sea-level change refers to the change in mean sea level relative to the geoid and is associated with the circulation and density-driven changes in the ocean. Ocean dynamic sea-level change varies regionally but by definition has a zero global mean. It includes the depression of the sea surface by atmospheric pressure. There is *medium confidence* in the understanding of ocean processes leading to dynamic sea-level change (Section 9.2.4.2).

Changes in Earth Gravity, Earth Rotation and viscoelastic solid Earth Deformation (GRD) result from the redistribution of mass between terrestrial ice and water reservoirs and the ocean. Contemporary terrestrial mass loss leads to elastic solid Earth uplift and a nearby relative sea-level fall (for a single source of terrestrial mass loss this is within ~2000 km, for multiple sources the distance depends on the interaction of the different relative sea-level patterns). Farther away (more than ~7000 km for a single source of terrestrial mass loss), relative sea level rises more than the global average, due, to first order, to gravitational effects. Earth deformation associated with adding water to the ocean and a shift of the Earth's rotation axis towards the source of terrestrial mass loss leads to second-order effects that increase spatial variability of the pattern globally. GRD effects due to the redistribution of ocean water within the ocean itself are referred to as ***self-attraction and loading effects***. There is *high confidence* in the understanding of GRD processes.

Glacial Isostatic Adjustment is ongoing GRD in response to past changes in the distribution of ice and water on Earth's surface. On a timescale of decades to tens of millennia following mass redistribution, Earth's mantle flows viscously as it evolves toward isostatic equilibrium, causing solid Earth movement and geoid changes, which can result in regional to local sea-level variations. There is *medium confidence* in the understanding of glacial isostatic adjustment processes.

Vertical land motion is the change in height of the land surface or the sea floor and can have several causes in addition to elastic deformation associated with contemporary GRD and viscoelastic deformation associated with glacial isostatic adjustment. Subsidence (sinking of the land surface or sea floor) can occur through compaction of alluvial sediments in deltaic regions, removal of fluids such as gas, oil, and water, or drainage of peatlands. Tectonic deformation of the Earth's crust can occur as a result of earthquakes and volcanic eruptions. There is *medium confidence* in the understanding of vertical land motion processes.

[3] The conversion of land ice mass loss to global mean sea-level rise used in this report (the Sea Level Equivalent, SLE) is 362.5 gigatons (Gt) of ice loss for 1 mm of sea-level rise

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Extreme sea level is an exceptionally low or high local sea-surface height arising from combined short-term phenomena (e.g. storm surges, tides and waves). Relative sea-level changes affect extreme sea levels directly by shifting the mean water levels and indirectly by modulating the depth for propagation of tides, waves and/or surges. Extreme sea levels can be influenced by changes in the frequency, tracks, or strength of weather systems, or anthropogenic changes such as dredging. ***Extreme Still Water Level*** refers to the combined contribution of relative sea-level change, tides and storm surges. Wind-waves also contribute to coastal sea level. ***Extreme Total Water Level*** is the extreme still water level plus wave setup (time-mean sea-level elevation due to wave energy dissipation). When considering coastal impacts, swash (vertical displacement up the shore-face induced by individual waves) is also important and included in ***Extreme Coastal Water Level***. There is *low* to *medium confidence* in the understanding of extreme sea level processes (Sections 9.6.4, 12.4).

[END BOX 9.1 HERE]

9.2 Oceans

9.2.1 Ocean surface

9.2.1.1 Sea Surface Temperature (SST)

The AR5 (Hartmann et al., 2013) assessed that it is certain that global sea-surface temperature (SST) has increased since the beginning of the 20th century (*very high confidence*). The SROCC did not assess past SST change. Since the AR5, improvements in the understanding of recent SST biases in the observational records, especially extending ship-based observations with buoy-based observations and improved treatment of sea ice, have had important consequences for key climate change indicators such as global mean surface temperature (GMST), global mean surface air temperature (GSAT), and SST (Cross-Chapter Box 2.3). The AR5 assessment is confirmed, and it is now *very likely* that global mean SST changed by 0.88°C [0.68-1.01°C] from 1850-1900 to 2011-2020, and 0.60°C [0.44-0.74°C] from 1980 to 2020 (Figure 9.3, Table 2.4).

Regions vary in the rate of SST warming, with slight cooling in some regions (Figure 9.3). The SROCC (Collins et al., 2019) and Section 7.4.4 assess SST changes over specific regions, which are consistent with the changes reported here. The tropical ocean has been warming faster than other regions since 1950, with the fastest warming in regions of the tropical Indian and western Pacific Oceans (Figure 9.3), due to a combination of local atmosphere-ocean coupling, the Indonesian Throughflow (Section 9.2.3.4; Figure 9.11), and trends in the Walker circulation (Section 2.3.1.4.1; Section 3.3.3.1; Figure 3.16). The Western Boundary Currents of the subtropical gyres have warmed faster than the global mean over the past century. There remains *low agreement* in the changes of both the location and the dynamical changes in western boundary current extensions (Sections 2.3.3.4.2, 9.2.3.4, Figure 9.3). In the Arctic, the mean SST increase over the last two decades is similar to or only slightly higher than the global average (Chen et al., 2019b). In contrast, the eastern Pacific Ocean, subpolar North Atlantic Ocean and Southern Ocean have warmed more slowly than the global average or cooled. (Figure 9.3). Surface warming in the subpolar Southern Ocean has been slower than the global average since the 1950s, and this pattern is consistent with the upwelling around Antarctica renewing surface water with pre-industrial, deeper water-masses (Section 9.2.3.2) (Frölicher et al., 2015; Marshall et al., 2015b; Armour et al., 2016). New evidence since the SROCC (Meredith et al., 2019) confirms slight cooling since the 1980s around the subpolar Southern Ocean, contrasting with marked warming directly northward of it (Section 9.2.3.2) (Haumann et al., 2020; Rye et al., 2020; Auger et al., 2021). In Eastern Boundary Upwelling Systems, the SROCC (Bindoff et al., 2019) reported *low agreement* between SST trends in recent decades, due to varying spatio-temporal resolution and interannual to multi-decadal variability. Satellite evidence not included in SROCC show that 92% of these regions warmed more slowly than neighbouring offshore locations between 1982-2015, so upwelling may buffer the near shore from warming (Varela et al., 2018) (Section 9.2.3.5). Coupled ocean-atmospheric modes of variability strongly affect regional SST (Cross-Chapter Box 3.1, Annex IV). In summary, a positive SST trend since 1950 is evident globally, but there is *very high confidence* that the Indian Ocean, western equatorial Pacific

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Ocean, and western boundary currents have warmed faster than the global average, while the Southern Ocean, the eastern equatorial Pacific, and the North Atlantic Ocean have warmed more slowly or slightly cooled.

[START FIGURE 9.3 HERE]

Figure 9.3: Sea Surface Temperature (SST) and its changes with time. (a) Time series of global mean SST anomaly relative to 1950-1980 climatology. Shown are observational reanalyses (HadISST) and multi-model means from the CMIP historical, CMIP projections, and HighResMIP experiment. (b) Map of observed SST (1995-2014 climatology HadISST), (e) bias of CMIP and (h) bias of HighResMIP (bottom left) over 1995-2014. Also shown are 1950-2014 c) historical SST changes from observations, (f) CMIP and (i) HighResMIP, and (d) 2005-2100 SST change rate, (g) 2005-2050 change rate for SSP5-8.5 for the CMIP ensemble, and (j) 2005-2050 change rate for SSP5-8.5 for the HighResMIP ensemble. No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.3 HERE]

In the AR5 (Flato et al., 2013), a marginal improvement in CMIP5 climate model SST biases was noted compared to CMIP3 models in the AR4, with a reduction in the magnitude of biases. The AR5 noted that in several regions large SST biases are symptomatic of errors in the representation of important processes, such as dynamics in the equatorial Pacific and North Atlantic, and Southern Ocean. Common regional biases in SST or historical SST trends are not exclusively linked to the representation of the ocean (*high confidence*), but can have multiple causes, including errors in the representation of long term historical trends in equatorial winds (Section 9.2.1.2); misrepresentation of the forced equatorial ocean response (Karnauskas et al., 2012; Kohyama et al., 2017; Coats and Karnauskas, 2018); thermocline depth errors (Linz et al., 2014); errors in atmospheric model cloud-related short-wave radiation (Hyder et al., 2018); biases in ocean circulation variability (Wang et al., 2014a); and deficiencies in upper ocean (Li et al., 2019b) and atmospheric (Bates et al., 2012) boundary layer parameterizations. In CMIP6, the mid-latitude biases in the northern hemisphere are improved in the multi-model mean and the inter-model standard deviation of the zonal mean SST error is significantly decreased in the northern Hemisphere south of 50°N compared to CMIP5, though biases in equatorial regions remains essentially unchanged (Section 3.5.1.1; Figures 3.23, 3.24, 9.3). Some longstanding ocean model biases have been reduced through increases in model resolution in CMIP6 (Bock et al., 2020) and improved parameterizations (Fox-Kemper et al., 2011; Li et al., 2016a; Qiao et al., 2016; Reichl and Hallberg, 2018). The high resolution HighResMIP ensemble (Figure 9.3) has smaller cold biases in the North Atlantic and the tropical Pacific, and smaller warm biases in the upwelling regions off the western coasts of Africa, North and South America (Roberts et al., 2018, 2019; Caldwell et al., 2019; Docquier et al., 2019). In summary, CMIP6 models show persistent regional biases in representing the climatological SST state (*very high confidence*), but higher resolution reduces some biases particularly in the North Atlantic and Eastern Boundary Upwelling Systems (Figure 9.3; *high confidence*).

CMIP6 models represent the observed trends in SST patterns with greater fidelity than CMIP5, with the ocean area that is inconsistent with the observed trends decreasing by about three quarters from CMIP5 to CMIP6 (Olonscheck et al., 2020). In some regions, the direction of SST changes in observations are consistent with CMIP6 only when including internal variability (Olonscheck et al., 2020). This is notably the case in the equatorial Pacific, North Atlantic, and Southern Ocean, which are regions where SST is of known importance in controlling heat uptake (Section 9.2.2.1) and the global radiative feedback parameter (Section 7.4.4.3). Overall, despite some persistent regional biases, CMIP6 coupled climate models reproduce the observed SST trends or high internal variability over the past century over a range of different multidecadal periods (Olonscheck et al., 2020; Watanabe et al., 2021) (Figure 9.3), highlighting their skill to inform future large-scale SST changes at regional scale. Warming is projected at varying rates in all regions by 2050, except the North Atlantic Subpolar Region, the equatorial Pacific, and the Southern Ocean where models

ACCEPTED VERSION SUBJECT TO FINAL EDITING

disagree (*high confidence*).

It is *virtually certain* that SST will continue to increase in the 21st century at a rate depending on future emission scenario. The future global mean SST increase projected by CMIP6 models for the period 1995-2014 to 2081-2100 is 0.86°C (5-95% range: 0.43-1.47°C) under SSP1-2.6, 1.51 °C [1.02-2.19°C] under SSP2-4.5, 2.19°C (1.56-3.30°C) under SSP3-7.0, and 2.89°C (2.01-4.07°C) under SSP5-8.5 (Figure 9.3). While under SSP1-2.6, the CMIP6 ensemble consistently projects that it is *very likely* at least 83% of the world ocean surface will have warmed by 2100, under SSP5-8.5, at least 98% of the world ocean surface will have warmed. The spatial pattern of future change is consistent with observed SST change over the 20th century, though with notable regional differences (Figure 9.3). Long-term change in SST patterns is important for regional impacts but also affects radiative feedbacks, and therefore long-term change in climate sensitivity (Section 7.4.4.3). In the Southern Ocean, CMIP6 models project that SSTs will eventually consistently increase in the 21st century at a rate dependent on future scenario (Bracegirdle et al., 2020) (Figure 9.3, Section 9.2.3.2). Yet, there is only *low confidence* that this Southern Ocean warming will emerge by the end of the century (Section 7.4.4.1), due the inconsistent historical and near-term simulations and observations over the 20th century (Figure 9.3). Furthermore, the equilibrium SST pattern from proxy records or simulated by climate models under CO_2 forcing stand in contrast with the cooling trends in the Southern Ocean observed over the past decades (Section 7.4.4.1.2). Similarly, the SST change pattern observed in the tropical Pacific Ocean will transition on centennial timescales to a mean pattern resembling the El Niño pattern (*medium confidence*, Annex IV). However, it is difficult to delineate a climate change trend ressembling an El Niño pattern and El Niño variability (Wittenberg, 2009; Collins et al., 2010) without large ensembles (Kay et al., 2015). Several Pliocene SST reconstructions indicate enhanced warming in the centre of the eastern Pacific equatorial cold tongue upwelling region, consistent with reconstruction of enhanced subsurface warming and enhanced warming in coastal upwelling regions (Section 7.4.4.2.2). The North Atlantic subpolar gyre is projected to continue to warm more slowly than surrounding regions (Suo et al., 2017), as the Gulf Stream concurrently warms rapidly (Cheng et al., 2013) (Figure 9.3) and the Atlantic Meridional Overturning Circulation further declines under greenhouse gas forcing although models disagree about the rate of change (Figure 9.3, Section 9.2.3.1). In summary, CMIP6 models show a future pattern of SST change comparable to historical trends with intensity depending on future emission scenario, and some of the observed cooling trends over the 20th century will eventually transition to a warming SST on centennial timescales, in particular in the Southern Ocean (*high confidence)* and in the equatorial Pacific (*medium confidence*), while the North Atlantic subpolar gyre will continue to warm more slowly than the global average (*high confidence)*.

9.2.1.2 Air-sea fluxes

Air-sea fluxes of energy, freshwater, and momentum (wind stresses) are difficult to observe directly (Cronin et al., 2019), so estimates of the global mean net air-sea heat flux are inferred from observed ocean warming (Section 2.3.3.1, Box 7.2, and Cross-Chapter Box 9.1). Air-Sea heat fluxes resemble the warming patterns of CMIP3 (Domingues et al., 2008; Levitus et al., 2012) and are consistent with the ensemble mean warming rate of CMIP5 (Cheng et al., 2017, 2019) and CMIP6 models (Section 3.5.1.3). Regional air-sea fluxes in models remain a key driver of uncertainty (Huber and Zanna, 2017; Tsujino et al., 2020). A substantial part of the upper 700 m energy increase is *very likely* attributed to anthropogenic forcing via increasing radiative forcing (Sections 3.5.1.3, 7.2, 7.3).

The SROCC (Abram et al., 2019) and AR5 (Rhein et al., 2013) assessed that observations of air-sea fluxes had not yet reached the density or accuracy to directly detect trends beyond the noise. New evidence since SROCC confirms that direct heat and freshwater flux trends have not emerged yet as spatial (Figure 9.4), annual (Yu, 2019), and decadal (Zanna et al., 2019a) variability overwhelm detection. Since the AR5, comprehensive comparisons (Bentamy et al., 2017; Valdivieso et al., 2017; Yu et al., 2017) have used updated and new surface flux products to improve surface flux uncertainty estimates, and these comparisons note that implied global energy imbalances often exceed the observed ocean warming. Flux estimates using top of atmosphere observations and atmospheric fluxes from reanalysis have improved over past products (Trenberth and Fasullo, 2018) but require consistency adjustments (Trenberth et al., 2019) as the energy

ACCEPTED VERSION SUBJECT TO FINAL EDITING

budget is not closed. Adjustments are needed for all flux products, and they remain less accurate than direct ocean heat content change measurements (Cheng et al., 2017). Some regional changes are *likely* robust in both satellite observations and projections (Figure 9.4). Recent satellite-based surface flux products with improved retrieval algorithms and new satellites, e.g., J-OFURO3 (Tomita et al., 2019) and OAFlux-HR (Yu, 2019), provide a complete suite of turbulent fluxes including heat, moisture, and momentum. When combined with satellite-based surface radiation from CERES EBAF (Kato et al., 2018) and precipitation from GPCP (Adler et al., 2003), full ocean-surface forcing is available since 1987 (Figure 9.4). These products agree with sparse buoy and ship observations within 30 W m^{-2} (Bentamy et al., 2017; Cronin et al., 2019). While patterns agree between models and satellites in net fluxes (Figure 9.4), the trend magnitudes are substantially weaker in models. The fluxes tending to warm the North Atlantic and Southern Ocean are consistent with the largest changes observed in the surface properties and water-masses (Sections 9.2.1.1, 9.2.2.1, 9.2.2.3). The observed trend toward a saltier Atlantic Ocean and a fresher Indian Ocean as well as trends in evaporation minus precipitation (E-P) patterns in the equatorial Pacific (see also Section 8.3.1) enhance the present mean pattern of wetting and drying. Elsewhere patterns are less clear with only partial, large-scale agreement with the wet gets wetter simplification (Sections 3.3.2.2, 4.4.1, 4.5.1). In summary, globally-integrated and large-scale fluxes are more reliably inferred from heat content and salinity change, while regional trends are rarely robust in observations and where robust tend to be underestimated or in disagreement in models (*very high confidence*).

[START FIGURE 9.4 HERE]

Figure 9.4: Global maps of observed mean fluxes (a, d, g), the observed trends in these fluxes (b, e, h) and the projected rate of change in these fluxes from SSP5-8.5 (c, f, i). Shown are the freshwater flux (a, b, c), net heat flux (d, e, f), and momentum flux or wind stress magnitude (g, h, i), with positive numbers indicating ocean freshening, warming, and accelerating respectively. The means and observed trends are calculated between 1995-2014 (freshwater and wind stress) or 2001-2014 (heat) and the SSP5-8.5 projected rates are between 1995-2100 using 20-year averages at each end of the time period. Observations show objective interpolation from CERES EBAF v4 (Kato et al., 2018), OAFlux-HR (Yu, 2019), and GPCP (Adler et al., 2003) of fluxes and flux trends. (b, e, h) Observed trends with no overlay indicates regions where the trends are significant at $p = 0.34$ level. Crosses indicate regions where trends are not significant. For (c, f, i) projections, no overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change, diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.4 HERE]

There is *low confidence* in long-term wind stress trends in most regions, but a few locations have *likely* trends over the scatterometer era and in projections, as shown in Figure 9.4 (Desbiolles et al., 2017; Young and Ribal, 2019; Yu, 2019). The AR5 (Rhein et al., 2013) assessed with *medium confidence* that zonal wind stress over the Southern Ocean increased from the early 1980s to the 1990s (Figure 9.4, *medium confidence*). Over 1995-2014, the zonal wind stress over the Southern Ocean continued to increase, westerly winds in the North Pacific and North Atlantic weakened while the easterly equatorial Pacific winds of the Walker circulation strengthened (Figure 9.4). In historical simulations, CMIP5 models projected annular modes (Annex IV) to move poleward and strengthen in both hemispheres (Yang et al., 2016a), while in CMIP6 models westerlies only strengthen over the Southern Ocean, with a weaker trend than recently observed (Figure 9.4, Sections 4.5.1, 4.5.3). In the tropical Pacific Ocean, a weakening trend in easterly winds and Walker circulation in the 20th century has been inferred based on observed sea level pressure data (Vecchi et al., 2006; Vecchi and Soden, 2007) and coral proxies (Carilli et al., 2014) and is projected to continue by CMIP6 models (Figure 9.4), yet over 1995-2014 observed winds have strengthened (Figure 9.4). The observed strengthening may have been influenced by a combination of factors (Section 7.4.4.2.1), but there is *low confidence* in the attribution of this signal to anthropogenic warming (Section 3.3.3.1) and *medium confidence* that it reflects internal variability (Section 8.3.2.3). Near-term projected changes over the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Southern Ocean result from ozone recovery and greenhouse gases (Sections 4.3.3, 4.4.3). Overall, there is only *low confidence* in observed and projected wind stress trends in most regions because trends in oceanic wind stresses during the satellite era have not emerged or are inconsistent with historical simulated changes.

Air-sea flux biases result from common causes in most models, many are the same as during AR5 (Rhein et al., 2013). Important currents (e.g., Gulf Stream, Kuroshio, Antarctic Circum-polar Current patterns) are often found in erroneous locations in models, affecting SST and flux signatures (Bates et al., 2012; Beadling et al., 2020; Li et al., 2020b), but their locations are improved in high-resolution ocean models (Chassignet et al., 2017, 2020; Hewitt et al., 2020), and high-resolution coupled models reduce the mean air-sea flux biases (Delworth et al., 2012; Sakamoto et al., 2012; Small et al., 2014a; Haarsma et al., 2016; Caldwell et al., 2019; Jackson et al., 2020a). Oceanic variability stems either from internal chaotic variability or atmospheric forcing (Hasselmann, 1976; Sérazin et al., 2016, 2017). Large scale variability in the ocean tends to follow atmospheric forcing in low resolution models, while in high-resolution coupled models ocean variability drives atmospheric variability on small scales (Bishop et al., 2017; Small et al., 2019), allowing these high-resolution models to mimic the coupling with clouds, precipitation, and atmospheric and oceanic boundary layers apparent in observations (Chelton and Xie, 2010; Frenger et al., 2013). Even coarse resolution models, such as the ocean and sea-ice components used in CMIP6, show significant sensitivity in the mean and variability of SST and sea ice to modest changes in flux forcing (Tsujino et al., 2020). Finally, there is still considerable disagreement between different parameterizations of air-sea fluxes used in models and strong scatter in direct observations (Renault et al., 2016; Brodeau et al., 2017). In summary, there is *very high confidence* that air-sea heat flux and stress biases are reduced in coupled models with high ocean resolution over coarse resolution models, although the effect on trends remain unclear.

9.2.1.3 Upper Ocean Stratification and Surface Mixed Layers

The density difference from surface to deep ocean is the upper-ocean stratification. The AR5 (Rhein et al., 2013) assessed that it is *very likely* that the thermal contribution to stratification over the fixed 0-200 m layer increased by about 1% per decade between 1971 and 2010 (based on linear trend consistently across reports). The SROCC (Bindoff et al., 2019) found it *very likely* that density stratification increased by 0.46-0.51% per decade between 60°S and 60°N from 1970 to 2017). New published estimates based on a variety of different interpolated observations show that the SROCC assessed rate is too low, even using the same data and methods (Li et al., 2020a). The 1960-2018 stratification increase is estimated at 1.2±0.1% per decade from the IAP product, 1.2±0.4% per decade from the Ishii product, 0.7±0.5% per decade from the EN4 product, 0.9±0.5% per decade from the ORAS4 product, and 1.2 ±0.3% per decade from the NCEI product (Li et al., 2020a). The improved methodology of computing stratification change on individual profiles before gridding yields a global annual mean increase of 0-200 m stratification change of 0.8±0.2% per decade between 1960 and 2018 (Yamaguchi and Suga, 2019) and a global summer mean increase of 0-200 m stratification change of 1.3±0.3% per decade between 1970 and 2018 (Sallée et al., 2021)is of a similar magnitude to the long term trend (Yamaguchi and Suga, 2019; Li et al., 2020a). In summary, there is *limited evidence* that focusing on changes over a fixed depth range might hide larger increases occurring at the seasonally and regionally variable pycnocline depth. There is also *limited evidence* that summer stratification change within the pycnocline has occurred at a rate of 8.9±2.7% per decade from 1970 to 2018, and *limited evidence* of a winter pycnocline stratification increase (Cummins and Ross, 2020a; Sallée et al., 2021).

[START FIGURE 9.5 HERE]

Figure 9.5: Mixed layer depth in (a-d) winter and (e-h) summer. (a, e) Observed climatological mean mixed layer depth (based on density threshold) from the Argo Mixed Layer Depth (Holte et al., 2017) observations 2000-2019. (b, f) Bias between the observation-based estimate (2000-2019) and the 1995-2014 CMIP6 climatological mean mixed layer depth. (c, d, g, h) Projected MLD change from 1995-2014 to 2081-2100 under (c, g) SSP1-2.6 and (d, h) SSP5-8.5 scenarios. The (a, b, c, d) Winter row shows DJF in the Northern Hemisphere and JJA in the Southern Hemisphere, and the (e, f, g, h) Summer row shows JJA in the Northern Hemisphere and DJF in the Southern Hemisphere. The mixed layer depth is the depth where

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the potential density is 0.03 kg m^{-3} denser than at 10m. No overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.5 HERE]

While AR5 and the SROCC did not assess change in mixed-layer depth, the reported changes in stratification can modulate the surface mixed layer depth, which is set by a balance between fluxes and dynamical mixing (winds, tides, waves, convection) acting against the background stratification and restratification processes (solar and dynamical). Despite the large stratification increase observed at a global scale, new evidence shows that summer mixed-layer depth deepened consistently over the globe at a rate of 2.9±0.5% per decade from 1970 to 2018, with the largest deepening observed in the Southern Ocean, corresponding to overall deepening from 3-15 m per decade depending on region (Somavilla et al., 2017; Sallée et al., 2021). While the shorter observational record in winter than in summer does not allow global winter mixed-layer trends to be reliably assessed (Sallée et al., 2021), winter mixed-layer depths deepening at rates of 10 m per decade have been reported at individual long-term mid-latitude monitoring sites (Somavilla et al., 2017). Projections agree that shoaling of mixed layer depth is expected in the 21st century, but only for strong emissions scenarios and only in some regions (Figure 9.5). In summary, there is *limited* observational *evidence* that the mixed layer is globally deepening, while models show no emergence of a trend until later in the 21st century under strong emissions.

The SROCC assessed that upper ocean stratification will continue to increase in the 21st century under increased radiative forcing (*high confidence*), due to increased surface temperature and high-latitude surface freshening (Bindoff et al., 2019). New climate model simulations concur with the SROCC assessment of a future increase of the 0-200 m stratification under increased radiative forcing in all regions of the world ocean (Kwiatkowski et al., 2020). In addition, CMIP6 climate models project a shallowing of the mixed-layer both in summer and winter by the end of the century under increased radiative forcing (Kwiatkowski et al., 2020) (Figure 9.5), with the exception of the Arctic showing deepening of the mixed-layer as a result of sea-ice retreat (Lique et al., 2018a) (Figure 9.5). The regions of largest shallowing are associated with the deepest climatological mixed layer both in winter and summer, particularly affecting the North Atlantic and the Southern Ocean basins (Figure 9.5). While CMIP6 models tend to project shallowing mixed-layers under a warming climate, except at high latitudes (Figure 9.5) (Lique et al., 2018b; Kwiatkowski et al., 2020), a deepening in the summer mixed-layer depth by intensification of the surface winds and storms may explain inconsistency among models in many regions (Figure 9.5) (Young and Ribal, 2019), although model mixed layer biases are large in the summertime in the Southern Ocean (Belcher et al., 2012; Sallée et al., 2013a; Li et al., 2016a; Tsujino et al., 2020). Lack of observed ocean turbulence and climate model limitations do not allow for direct assessment of ocean surface turbulence change and limit confidence in past and future mixed-layer change. Understanding of turbulent processes, its representation in ocean and climate models, and its effect on mixed layer biases have been an active and rapidly evolving topic of research since AR5 (Buckingham et al., 2019; Li et al., 2019b). Small-scale mixed layer processes are not resolved in climate models (D'Asaro, 2014; Buckingham et al., 2019; McWilliams, 2019) and despite significant improvements in their parameterisation over the last decade (Fox-Kemper et al., 2011; Jochum et al., 2013; Li et al., 2016a; Qiao et al., 2016; Li et al., 2019b) and significant improvement in some models (Li and Fox-Kemper, 2017; Dunne et al., 2020), biases in mixed-layer representation generally persist (Heuzé, 2017; Williams et al., 2018; Cherchi et al., 2019; Golaz et al., 2019; Voldoire et al., 2019; Yukimoto et al., 2019; Boucher et al., 2020; Danabasoglu et al., 2020; Dunne et al., 2020; Kelley et al., 2020). In summary, the representation of upper ocean stratification and mixed layers has improved in CMIP6 compared to CMIP5. While it is *virtually certain* that the global mean upper ocean will continue to stratify in the 21st century, there is only *low confidence* in the future evolution of mixed-layer depth, which is projected to mostly shoal under high emissions scenarios except in high latitude regions where sea-ice retreats.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[START BOX 9.2 HERE]

BOX 9.2: Marine Heatwaves

Marine heatwaves (MHW) are periods of extreme high sea temperature relative to the long-term mean seasonal cycle (Hobday et al., 2016). Studies since the SROCC (Collins et al., 2019) confirm the assessment that MHW can lead to severe and persistent impacts on marine ecosystems, from mass mortality of benthic communities including coral bleaching, changes in phytoplankton blooms, shifts in species composition and geographical distribution, toxic algal blooms to decline in fisheries catch and mariculture (Smale et al., 2019; Cheung and Frölicher, 2020; Hayashida et al., 2020a; Piatt et al., 2020). Unlike synoptic atmospheric heatwaves (Section 11.3), MHWs can extend for millions of square kilometres, persist for weeks to months, and occur at subsurface (Bond et al., 2015; Schaeffer and Roughan, 2017; Perkins-Kirkpatrick et al., 2018; Laufkötter et al., 2020).

The SROCC established that MHWs have occurred in all basins over the last decades. Additional evidence documenting widespread occurrence of marine heat waves in all basins and marginal seas continues to accumulate (Li et al., 2019c; Yao et al., 2020). The SROCC highlighted the role of large-scale climate modes of variability in amplifying or suppressing MHW occurrences, which has since been further corroborated, increasing confidence in climate modes as important drivers of MHWs (Holbrook et al., 2019; Sen Gupta et al., 2020). More generally, understanding of processes leading to MHWs has increased since the SROCC, including air-sea heat flux (Section 9.2.1.2), increased horizontal heat advection, shoaling of the mixed layer and suppressed mixing processes (Section 9.2.1.3), reduced coastal upwelling and Ekman pumping (Section 9.2.3.5), changes in eddy activities and planetary waves, and the re-emergence of warm subsurface anomalies (Holbrook et al., 2020; Sen Gupta et al., 2020).

The SROCC reported with *high confidence* that MHWs (defined as days exceeding the 99th percentile in SST from 1982 to 2016) have *very likely* doubled in frequency between 1982 and 2016. Additional observation-based evidence and acquisition of longer observation time-series since the SROCC have confirmed and expanded on this assessment: since the 1980s MHWs have also become more intense and longer (Frölicher and Laufkötter, 2018; Smale et al., 2019; Laufkötter et al. 2020). Satellite observations and reanalyses of SST show increase in intensity of 0.04°C per decade from 1982 to 2016, an increase in spatial extent of 19 % per decade from 1982 to 2016, and an increase in annual MHW days of 54 % between the 1987-2016 period compared to 1925-1954 (Frölicher et al., 2018; Oliver, 2019). The SROCC assessed that 84-90% of all MHWs that occurred between 2006 and 2015 are *very likely* caused by anthropogenic warming. There is new evidence since SROCC that the frequency of the most impactful marine heatwaves over the last few decades has increased more than 20-fold because of anthropogenic global warming (Laufkötter et al., 2020). In summary, there is *high confidence* that MHWs have increased in frequency over the 20th century, with an approximate doubling from 1982-2016, and *medium confidence* that they have become more intense and longer since the 1980s.

[START BOX 9.2, FIGURE 1 HERE]

Box 9.2, Figure 1: Observed and simulated regional probability ratio of marine heatwaves (MHWs) for the 1985-2014 period and for the end of the 21st century under two different greenhouse gas emissions scenarios. The probability ratio is the proportion by which the number of MHW days per year has increased relative to pre-industrial times. A MHW is defined as a deviation beyond the daily 99th percentile (11-day window) in the deseasonalized sea surface temperature. (a) The MHW probability ratio from satellite observations (NOAA OISST V2.1; (Huang et al., 2021) during 1985-2014. The mean warming pattern (difference in ERSST5 (Huang et al., 2017) sea surface temperature between the 1985-2014 and 1854-1900 periods) has been added to the satellite observations to calculate the probability ratio. (b-d) CMIP6 simulated multi-model mean probability ratio of the (b) 1985-2014 period, and 2081-2100 period in the (c) SSP1 2.6 and (d) SSP5 8.5 scenarios. The areas with grey diagonal lines in (d) indicate permanent MHWs (> 360 heatwave days per year). These 14 CMIP6 models are included in the analysis: ACCESS-CM2, CESM2, CESM2-WACCM, CMCCCM2-SR5, CNRM-CM6-1, CNRM-ESM2-1, CanESM5, EC-Earth3,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

IPSL-CM6A-LR, MIROC6, MRI-ESM2-0, NESM3, NorESM2-LM, NorESM2-MM. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END BOX 9.2, FIGURE 1 HERE]

Consistent with the SROCC, future MHWs are defined with reference to the historical climate conditions. The SROCC assessed that MHWs will *very likely* further increase in frequency, duration, spatial extent and intensity under future global warming in the 21st century. CMIP6 projections allow us to confirm this assessment and quantify future change based on global mean probability ratio change (Box 9.2, Figure 1): they project MHWs will become 4 (5-95% range: 2-9) times more frequent in 2081-2100 compared to 1995-2014 under SSP1-2.6, or 8 (3-15) times more frequent under SSP5-8.5. The SROCC highlighted that future change of MHWs will not be globally uniform, with the largest changes in the frequency of marine heatwaves being projected to occur in the western tropical Pacific and the Arctic Ocean (*medium confidence*). New evidence from the latest generation of climate models confirms and complements the SROCC assessment (Box 9.2, Figure 1). Moderate increases are projected for mid-latitudes, and only small increases are projected for the Southern Ocean (*medium confidence*) (Hayashida et al., 2020b). While under the SSP5-8.5 scenario, permanent MHWs (more than 360 days per year) are projected to occur in the 21st century in parts of the tropical ocean, the Arctic Ocean and around 45°S, the occurrence of such permanent MHWs can largely be avoided under the SSP1-2.6 scenario (Frölicher et al., 2018; Oliver et al., 2019; Plecha and Soares, 2020). The resolution of current climate models (CMIP5 and CMIP6) capture the broad features of MHWs, but they may have a bias towards weaker and longer MHWs in the historical period (*medium confidence*) (Frölicher et al., 2018; Pilo et al., 2019; Plecha and Soares, 2020) and greater intensification in western boundary current regions (Hayashida et al., 2020b).

[END BOX 9.2 HERE]

9.2.2 Changes in Heat and Salinity

9.2.2.1 Ocean Heat Content and Heat Transport

Ocean warming, i.e., changing ocean heat content, is an important aspect of energy on Earth: the SROCC (Bindoff et al., 2019) reported that there is *high confidence* that ocean warming during 1971-2010 dominated the increase in the Earth's energy inventory, which is confirmed by the Box 7.2 assessment that the ocean has stored 91% of the total energy gained from 1971 to 2018. As reported in Sections 2.3.3.1, 3.5.1.3 and 7.2.2.2, Box 7.2 and Cross-Chapter Box 9.1, confidence in the assessment of global ocean heat content (OHC) change since 1971 is strengthened compared to previous reports and extended backward to include *likely* warming since 1871. Table 7.1 updates the estimates of total ocean heat gains from 1971 to 2018, 1993 to 2018 and 2006 to 2018. Section 3.5.1.3 assesses that it is *extremely likely* that anthropogenic forcing was the main driver of the OHC increase over the historical period. Section 2.3.3.1 reports that current multidecadal to centennial rates of OHC gain are greater than at any point since the last deglaciation (*medium confidence*).

Ocean warming is not uniform with depth. The AR5 (Rhein et al., 2013) assessed that since 1971 ocean warming was *virtually certain* for the upper 700 m and *likely* for the 700-2000 m layer. Both the AR5 and the SROCC (Bindoff et al., 2019) assessed that the deep ocean below 2000 m had *likely* warmed since 1992, especially in the Southern Ocean. Section 2.3.3.1 provides an updated assessment of ocean temperature change for different depth layers, different time periods and different observation-based reconstructions (Table 2.7). Section 2.3.3.1 confirms the previous assessment that it is *virtually certain* that the upper ocean (0-700m) has warmed since 1971, that ocean warming at intermediate depths (700-2000 m) is *very likely* since 2006, and that it is *likely* that ocean warming has occurred below 2000 m since 1992. Section 3.5.1.3 assessed that it is *extremely likely* that human influence was the main driver of the ocean heat content increase observed since the 1970s, which extends into the deeper ocean (*very high confidence*), and shows

ACCEPTED VERSION SUBJECT TO FINAL EDITING

that biases in potential temperature have a complex pattern (Figure 3.25). In the present section, we assess the regional patterns of this warming and associated processes driving regional ocean warming.

The rate of ocean warming varies regionally, with some regions having experienced slight cooling (Figure 9.6). The SROCC (Bindoff et al., 2019) assessed that ocean warming in the 0-700 m is globally widespread, with slower than global average warming in the subpolar North Atlantic. The SROCC (Meredith et al., 2019) also estimated that the Southern Ocean accounted for ~75% of global ocean heat uptake during 1870–1995 and that 35-43% of the upper 2000 m global ocean warming occurred in the Southern Ocean over 1970-2017 (45-62% for 2005-2017). The SROCC noted that this interhemispheric asymmetry might at least partially be explained by high concentrations of aerosols in the northern hemisphere. Here, we confirm these assessments, bring new evidence attributing these regional trends, and discuss the role of decadal ocean circulation variability in redistributing heat, driving interhemispheric asymmetry of the recent rate of ocean warming (Rathore et al., 2020; Wang et al., 2021b). Since the SROCC, one new study shows that the subpolar North Atlantic "warming hole" observed since the 1980s has emerged from internal climate variability and can be attributed to greenhouse gas emissions (Chemke et al., 2020). A new analysis of a suite of climate models (Hobbs et al., 2020) confirms the SROCC assessment, based on one paper (Swart et al., 2018), attributing the observed Southern Ocean warming to anthropogenic forcing. Given the large fraction of global ocean warming in the Southern Ocean and the sparse observations there before 2005, there is *limited evidence* that global OHC increase since 1971 might have been underestimated (Cheng and Zhu, 2014; Durack et al., 2014). Cross-Chapter Box 9.1 accounts for an increased error before 2005 in global OHC change. In summary, in the upper 2000 m since the 1970s, the subpolar North Atlantic has been slowly warming, and the Southern Ocean has stored a disproportionally large amount of anthropogenic heat (*medium confidence*).

[START FIGURE 9.6 HERE]

Figure 9.6: Ocean heat content (OHC) and its changes with time. (a) Time series of global ocean heat content anomaly relative to a 2005-2014 climatology in the upper 2000m of the ocean. Shown are observations (Ishii et al., 2017; Baggenstos et al., 2019; Shackleton et al., 2020), model-observation hybrids (Cheng et al., 2019; Zanna et al., 2019a), and multi-model means from the CMIP6 historical (29 models) and SSP scenarios (label subscripts indicate number of models per SSP). (b-g) Maps of Ocean Heat Content across different time periods, in different layers, and from different data sets/experiments. Maps show the CMIP6 ensemble bias and observed (Ishii et al., 2017) trends of OHC for (b, c) 0-700m for the period 1971-2014, and (e, f) 0-2000m for the period 2005-2017. CMIP6 ensemble mean maps show projected rate of change 2015-2100 for (d) SSP5-8.5 and (g) SSP1-2.6 scenarios. Also shown are the projected changes in 0-700m OHC for (d) SSP1-2.6 and (g) SSP5-8.5 in the CMIP6 ensembles, for the period 2091-2100 versus 2005-2014. No overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.6 HERE]

Below 2000 m, direct observations of full-depth ocean temperature change are limited to ship-based, high-quality deep ocean temperature measurements. Such high quality full-depth ship-based sampling has improved from 1990 to the present due to the World Ocean Circulation Experiment (WOCE) and the Global Ocean Ship-based Hydrographic Investigations Program (GO-SHIP) (Sloyan et al., 2019). The SROCC (Bindoff et al., 2019) assessed that the *likely* warming of the ocean since the 1990s below 2000 m is associated with a marked regional pattern, with larger warming in the Southern Ocean. In the deep North Atlantic, warming has reversed to cooling over the past decade, possibly due to internal variability fed by North Atlantic Deep Water (Section 9.2.2.3). Over the past decade, the warming rate of Antarctic Bottom Water (AABW, Section 9.2.2.3) has been dependent on origin: slower from the Weddell Sea and faster from the Ross Sea and Adélie Land. One new study (Purkey et al., 2019a) strengthens confidence in AABW warming: below 4000 m a monotonic, basin-wide, and multidecadal temperature change is found in the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

southern Pacific basin, with larger warming rates near the bottom water formation sites than further downstream. New analysis of one model provides *limited evidence* that the sparse observational record may underestimate the rate of deep ocean warming over 1990-2010 by about 20% (Garry et al., 2019) which is included in the assessed OHC error (Cross-Chapter Box 9.1). There is still *low agreement* in deep ocean changes from ocean data-assimilation reanalyses (Palmer et al., 2017) and *low confidence* in such inferences. In summary, while observational coverage below 2000 m is sparser than in the upper 2000 m, there is *high confidence* that deep ocean warming below 2000 m has been larger in the Southern Ocean than in other ocean basins due to widespread AABW warming.

[START FIGURE 9.7 HERE]

Figure 9.7: Meridional-depth profiles of zonal-mean potential temperature in the ocean and its rate of change in the upper 2000m of the Global, Pacific, Atlantic, and Indian Oceans. Shown are (a, e, i, m) observed temperature (Argo climatology 2005-2014), (b, f, j, n) bias of the CMIP6 ensemble over this period, and future changes under (c, g, k, o) SSP1-2.6 and (d, h, l, p) SSP5-8.5. No overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.7 HERE]

Different processes drive OHC patterns over a range of timescales. Recent literature has highlighted the role of ocean circulation variability in driving OHC patterns by decomposing the global pattern of OHC change into a combination of added heat due to climate change taken up under fixed ocean circulation ("added heat"), and redistribution of heat associated with changing ocean currents ("redistributed heat") (Gregory et al., 2016; Bronselaer and Zanna, 2020; Couldrey et al., 2020). Redistributed heat alters regional patterns of heat storage (and carbon storage; Cross-Chapter Box 5.3) (Bronselaer and Zanna, 2020; Couldrey et al., 2020; Todd et al., 2020) but does not affect the global OHC. There is *medium confidence* that decadal variability of the ocean circulation strengthened the rate of ocean warming in the Southern Hemisphere compared to the Northern Hemisphere in the decade from 2005 (Rathore et al., 2020; Wang et al., 2020; Zika et al., 2021). More generally, since 2005, the OHC pattern observed is predominantly due to heat redistribution with regions of both warming and cooling (Zika et al., 2021) (Figure 9.6) but extending analysis back to 1972 shows the importance of added heat setting a large-scale warming pattern with mid-latitude maxima consistent with subduction of water masses, particularly in Southern Hemisphere Mode Waters (Section 9.2.2.3;Figures 9.6, 9.8) (Bronselaer and Zanna, 2020). The longer the analysis window, the more added heat dominates over redistributed heat. This translates into more ocean area with statistically significant warming trends and less area with statistically significant cooling trends (Johnson and Lyman, 2020). The region where added heat is most compensated for by redistributed cooling is in the northern North Atlantic basin, where changes in the subpolar gyre circulation and AMOC result in cooling (Section 9.2.3.1) (Williams et al., 2015b; Piecuch et al., 2017; Zanna et al., 2019a; Bronselaer and Zanna, 2020). In summary, and strengthening the SROCC assessment, ocean warming is not globally uniform due to patterns of uptake predominantly along known water mass pathways, and due to changing ocean circulation redistributing heat within the ocean (*high confidence*).

[START FIGURE 9.8 HERE]

Figure 9.8: Decomposition of ocean simulated ocean heat content and northward heat transport. (a, c, e) Total ocean heat content (0-2000 m) warming rate as observed and simulated by CMIP5 models over the historical period (1951-2011) and under the RCP8.5 future (2011-2060) versus the associated decomposed (b, d, f) added heat contribution (neglecting changes in ocean circulation) to the total (Bronselaer and Zanna, 2020). (g) Relationship between northward heat transport and Atlantic Meridional Overturning Circulation in HighResMIP models (1950-2050) and observations during the RAPID period

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(2004-2018). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.8 HERE]

While heat redistribution reflects changes in ocean circulation and is a useful concept to understand the underlying processes driving OHC patterns, change in ocean heat transport (OHT) arises due to changes in both ocean circulation and ocean temperature and affects regional OHC change. The AR5 did not assess change in OHT and the SROCC (Meredith et al., 2019) only assessed projected OHT increases into the Nordic Seas and the Arctic Ocean. New evidence of increasing northward OHT into the Arctic has been observed in recent decades (Muilwijk et al., 2018; Wang et al., 2019b; Tsubouchi et al., 2021), similar to the SROCC assessment, and consistent with observed increase in OHC in the ice free Arctic ocean (Mayer et al., 2019). It is estimated that an increase of 0.021 PW of OHT occurred after 2001 into the Arctic, which is sufficient to account for the recent OHC change in the northern seas (Tsubouchi et al., 2021). However, these trends cannot yet be attributed to anthropogenic forcing due to potential internal variability (Muilwijk et al., 2018; Wang et al., 2019b). New evidence strengthens the case that ENSO and the Northern Annular Mode affect interannual OHT variability (Trenberth et al., 2019) and shows that a slowing AMOC reduces northward OHT in the Atlantic at 26.5°N (Bryden et al., 2020) (Section 9.2.3.1, Figure 9.8). Despite a decrease of AMOC northward heat (0.17 PW) and mass (2.5 Sv) transport, OHT has increased toward the Arctic through increased upper northern North Atlantic temperatures and stronger wind-driven gyres (*medium confidence*) (Section 9.2.3.4, Figure 9.11) (Singh et al., 2017; Oldenburg et al., 2018a). In summary, OHT has increased toward the Arctic in recent decades, which at least partially explains the recent OHC change in the Arctic (*medium confidence*).

Major volcanic eruptions have caused interannual to decadal cooling phases within the marked long-term increase in global OHC (Agung in 1963, El Chichón in 1982 and Pinatubo in 1991; Cross-Chapter Box 4.1) (Church et al., 2005; Fasullo et al., 2016; Stevenson et al., 2016; Fasullo and Nerem, 2018). In the first few years following an eruption, heat exchange with the subsurface ocean allows atmospheric cooling to be sequestered into the seasonal thermocline, therefore reducing the magnitude of the peak atmospheric temperature anomaly (Gupta and Marshall, 2018). However, while explosive volcanic eruptions only disturb the Earth's radiative budget and surface fluxes for a few years, the ocean preserves an anomaly in OHC in the upper 500m (also affecting thermosteric sea level) many years after the eruption (Gupta and Marshall, 2018; Bilbao et al., 2019). The anomaly affects the atmosphere through air-sea heat fluxes with surface conditions returning to normal only after several decades (Gupta and Marshall, 2018; Bilbao et al., 2019), or on centennial time-scales in the case of repeated eruptions (Miller et al., 2012a; Atwood et al., 2016; Gupta and Marshall, 2018). In summary, there is *medium confidence* that oceanic mechanisms buffer the atmospheric response to volcanic eruptions on annual timescales by storing volcanic cooling in the subsurface ocean, affecting ocean heat content and thermosteric sea level on decadal to centennial timescales.

CMIP5 and CMIP6 models simulate OHC changes that are consistent with the updated observational and improved estimates of OHC over the period 1960 to 2018 (Figures 9.6, 9.7, 9.8), and they replicate the vertical partitioning of OHC change for the industrial era, although with a tendency to underestimate OHC gain shallower than 2000 m and overestimate it deeper than 2000 m (Section 3.5.1.3). The AR5 (Flato et al., 2013) assessed that climate models transport heat downward more than the real ocean. Since the AR5, studies have shown that increasing the horizontal resolution of ocean models tends to increase agreement of vertical heat transport with observations as the dependency on ad-hoc choices of eddy parameterizations is relaxed (Griffies et al., 2015; Chassignet et al., 2020). The magnitude of the AMOC and Indonesian Throughflow affect future OHC change, e.g. through overestimated modelled downward heat pumping (Kostov et al., 2014), and there are indications of greater model consistency in these transports at higher resolution (Chassignet et al., 2020; Jackson et al., 2020a) (Figure 9.10). Climate models tend to reproduce the observed added heat, but redistributed heat is less well represented (Figure 9.8) (Bronselaer and Zanna, 2020; Dias et al., 2020; Couldrey et al., 2021). Since redistributed heat dominates historical OHC change, historical simulations poorly reproduce regional patterns, but as future OHC change will become dominated

ACCEPTED VERSION SUBJECT TO FINAL EDITING

by added heat, more skill in future modelled OHC patterns is expected (Bronselaer and Zanna, 2020). In summary, climate models have more skill in representing OHC change from added heat than from ocean circulation change (*high confidence*). Since added heat dominates over redistributed heat on a centennial scale (especially under high emissions scenarios) confidence in future modelled OHC patterns at the end of the 21st century is greater than at decadal scale.

The SROCC (Bindoff et al., 2019) assessed that the ocean will continue to take up heat in the coming decades for all plausible scenarios, and here this assessment is confirmed with *very high confidence*. The SROCC reported that compared with the observed changes since the 1970s, the warming of the ocean by 2100 would *very likely* double to quadruple for low emissions scenarios (RCP2.6) and increase 5 to 7 times for high emissions scenarios (RCP8.5). The SROCC also concluded with *high confidence* that the overall warming of the ocean would continue this century even after radiative forcing and mean surface temperatures stabilize, and SROCC projected that ocean heat content in the 0–2000 m layer will increase from 2017 to 2100 by 0.900±0.345 YJ under RCP2.6 and 2.150±0.540 YJ under RCP8.5. Updating the SROCC estimates with CMIP6 projections gives heat content increases and 17-83% ranges in the 0–2000 m layer from 1995-2014 to 2081-2100 of 1.06 (0.80 – 1.31) YJ, 1.35 (1.08 – 1.67) YJ, 1.62 (1.37 – 1.91) YJ, 1.89 (1.60 – 2.29) YJ under scenarios SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5, respectively (Figure 9.6, Table 9.1). The two-layer model used here to calculate thermosteric sea level rise (9.SM.4) and tuned for AR6-assessed ECS (Section 7.SM.2), provides consistent 17-83% ranges of 1.18 (0.99 – 1.42) YJ, 1.56 (1.33 – 1.86) YJ, 1.90 (1.63 – 2.21) YJ, 2.23 (1.92 – 2.64) YJ under scenarios SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5- 8.5, respectively (Table 9.1). Based on both CMIP6 models and the two-layer model, it is *likely* that, from 1995-2014 to 2081-2100, OHC will increase 2 to 5 times the amount of the 1971-2018 OHC increase under SSP1-2.6, and 4 to 8 times that amount under SSP5-8.5. CMIP6 models show that the dependence of OHC on scenarios begins only after about 2040 (Figure 9.6).

The patterns of OHC projected by CMIP6 models (Figures 9.6, 9.7) are similar to the CMIP5 projections assessed in the SROCC (Bindoff et al., 2019): faster warming in all water mass subduction regions (e.g., subtropical cells and Mode waters); deeper penetration in the centre of subtropical gyres; slower northern North Atlantic warming due to slowing AMOC; and slower subpolar Southern Ocean warming due upwelled pre-industrial water masses. Decreased aerosol forcing will allow Northern Hemisphere ocean warming to be faster and less dominated by Southern Hemisphere change (Shi et al., 2018; Irving et al., 2019). Since the SROCC, distinguishing between added and redistributed heat has aided in understanding projections (Bronselaer and Zanna, 2020; Couldrey et al., 2020; Dias et al., 2020). The near-term decades will feature patterns strongly influenced by heat redistribution and internal variability (Rathore et al., 2020). Strengthening Southern Hemisphere westerlies are projected except for stringent mitigation scenarios (Bracegirdle et al., 2020) and will cause a northward and downward OHT. There is *low agreement* in future Southern Ocean warming across model results due to uncertainties in the magnitude of westerly wind changes (Figure 9.4) (Liu et al., 2018; He et al., 2019; Dias et al., 2020; Lyu et al., 2020b) and the degree of eddy compensation of overturning across different parameterisations and resolutions (9.2.3.2) (Beal and Elipot, 2016; Mak et al., 2017; Roberts et al., 2020a). By 2100 however, the OHC change will be dominated by the added heat response, particularly for strong warming scenarios (Garuba and Klinger, 2018; Bronselaer and Zanna, 2020) with added heat following unperturbed water mass pathways in the North Atlantic and Southern Ocean (Couldrey et al., 2020; Dias et al., 2020) (Figure 9.8). There is *high confidence* that projected weakening of the AMOC (Section 9.2.3.1) will cause a decrease in northward OHT in the northern hemisphere mid-latitudes (Figure 9.8; Sections 9.2.3.1,4.3.2.3; Weijer et al., 2020) associated with a dipole pattern of Atlantic OHC redistributed from northern to low latitudes that may override added heating in the northern North Atlantic (Figures 9.6, 9.7, 9.8). Variations in the degree of AMOC redistributed heat (Menary and Wood, 2018) causes large intermodel spread in SST (Figure 9.3) and OHC (Figure 9.6) change (Kostov et al., 2014; Bronselaer and Zanna, 2020; Couldrey et al., 2020; Todd et al., 2020). In the 700-2000m depth range, CMIP5 and CMIP6 models project the largest warming to be in the North Atlantic Deep Water and Antarctic Intermediate Water (Figure 9.7) while below 2000 m, the North Atlantic cools in many models, and Antarctic Bottom Waters warm (Sallée et al., 2013b; Heuzé et al., 2015). In summary, on decadal timescales, redistribution will dominate regional patterns of OHC change without affecting the globally integrated OHC, but by 2100, particularly under strong warming scenarios, there is *high confidence* that regional patterns of OHC change will be dominated by added heat entering the sea surface primarily in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

water-mass formation regions in the subtropics, with reduced aerosols increasing the relative rate of Northern Hemisphere heat uptake (*medium confidence*).

The SROCC assessed that the warming of the deep ocean is slow to manifest, with multi-century or longer response times, so global OHC (and global mean thermosteric sea level) will continue to rise for centuries (Figures 9.9, 9.30). New studies show that this continuation persists even after cessation of greenhouse gas emissions (Ehlert and Zickfeld, 2018a). Ocean warming will continue even after emissions reach zero because of slow ocean circulation (Larson et al., 2020). Ocean heat content will increase until at least 2300 even for low emission scenarios, but with a scenario-dependent rate (Nauels et al., 2017; Palmer et al., 2018) and depends not only on cumulative CO_2 emissions, but also on the time profile of emissions (Bouttes et al., 2013). Past long-term changes in total OHC illustrate adjustment relevant to expected future changes (Figure 9.9). Observational data (Figure 9.9) from ice core rare gas elemental and isotopic ratios document a rise in global OHC relative to the Last Glacial Maximum of >17,000 ZJ (change in mean ocean temperature >3.1ºC) (Bereiter et al., 2018; Baggenstos et al., 2019; Shackleton et al., 2019, 2020). This temperature increase is significantly larger than the modelled OHC changes associated with collapse of AMOC alone and tracks rising Southern Ocean SST (Uemura et al., 2018), strengthening of the deep abyssal overturning cell (Du et al., 2020) and increased North Atlantic water in the Southern Ocean (Wilson et al., 2020), underscoring the importance of Antarctic abyssal ventilation on long-term oceanic heat budgets (Section 9.2.3.2). An ensemble of four intermediate-complexity models project 10,000-year future responses to CO_2 emissions (Clark et al., 2016) with SST change peaking around 2300 with varying scenario-dependent magnitude approaching the scale of glacial-to-interglacial changes in paleodata (Figure 9.9). Long-term OHC commitments relative 1850-1900 conditions are 2.6, 9.7, 15.2, 21.6, and 28.0 YJ (with mean ocean temperature change as much as 5.1ºC) for emissions of 0, 1280, 2560, and 3840 and 5120 Gt after 2000 CE respectively, with OHC peaking near 4000 CE reflecting whole-ocean warming lagging SST by thousands of years. The exact timing is uncertain subject to rates of high-latitude meltwater input (Van Breedam et al., 2020) and circulation time (Gebbie and Huybers, 2019). In summary, there is *high confidence* that there is a long-term commitment to increased OHC in response to anthropogenic CO_2 emissions, which is essentially irreversible on human timescales.

[START FIGURE 9.9 HERE]

Figure 9.9: Long-term trends of ocean heat content and surface temperature. (a, b) Ice-core rare gas estimates of past mean ocean heat content OHC (ZJ), scaled to global mean ocean temperature (°C) and to steric GMSL (m) (red dashed line) are compared to surface temperatures (black solid line, gold solid line; °C rightmost axis). Southern Ocean SST from multiple proxies in 11 sediment cores and from ice core deuterium excess (Uemura et al., 2018). a) Penultimate glacial interval to last interglacial, 150,000-100,000 yr B2K (Shackleton et al., 2020). b) Last glacial interval to modern interglacial, 40,000-0 yr B2K (Baggenstos et al., 2019; Shackleton et al., 2019). Changes in OHC (dashed lines) track changes in Southern Ocean SST (solid lines). c) Long-term projected (2000 to 12000 CE) changes of OHC (dashed lines) in response to four greenhouse gas emissions scenarios (Clark et al., 2016) scale similarly to large-scale paleo changes but lag projected gobal mean SST (solid lines). d) model simulated 1500-1999 OHC (Gregory et al., 2006) and 1955-2019 observations (Levitus et al., 2012) updated by NOAA NODC. All data expressed as anomalies relative to pre-industrial time. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.9 HERE]

9.2.2.2 Ocean Salinity

The AR5 (Rhein et al., 2013) assessed that it was *very likely* that subsurface salinity changes reflect surface salinity change, and that basin-scale regions of high salinity and evaporation had trended more saline, while regions of low salinity and more precipitation had trended fresher since the 1950s. The SROCC (Bindoff et al., 2019) assessment was consistent with the AR5. Section 2.3.3.2 strengthens evidence that subsurface salinity trends are connected to surface trends (*very likely*), which are in turn linked to an intensifying

ACCEPTED VERSION SUBJECT TO FINAL EDITING

hydrological cycle (*medium confidence*) and increasing evidence from updated observational records indicates it is now *virtually certain* that surface salinity contrasts are increasing. At basin scale, Section 2.3.3.2 and the AR5 concur that it is *very likely* that the Pacific and Southern Ocean have freshened, and the Atlantic has become more saline. Figures 3.25 and 3.27 compare CMIP6 models to salinity observations.

Globally the mean salinity contrast at near-surface between high- and low- salinity regions increased 0.14 [0.07 to 0.20] from 1950 to 2019 (Section 2.3.3.2). At regional scale, the SROCC (Meredith et al., 2019) assessed an Arctic liquid freshwater trend of 600 ± 300 km^3 yr^{-1} (600 ± 200 Gt yr^{-1}) between 1992 and 2012, reflecting changes associated with continental freshwater imports that affect ocean mass (land ice, rivers) as well as changes in sea ice volume. Since the AR5, regional observation-based analyses not assessed in the SROCC further confirm the long-term, large-scale and regional patterns of salinity change, both at the ocean surface and in the subsurface ocean, including almost 120 years of changes in the North Atlantic (Friedman et al., 2017) and 60 years of monitoring in the subpolar North Pacific (Cummins and Ross, 2020b). These longer time-series also provide context to detect large multi-annual change, from 2012 to 2016 in the subpolar North Atlantic, unprecedented over the centennial record (Holliday et al., 2020). In summary, there is *high confidence* that salinity trends have extended for more than 60-100 years in the regions with long historical observation records such as the North Pacific and the North Atlantic basin.

While there is *low confidence* in direct estimates of trends in surface freshwater fluxes (Sections 2.3.1.3.5, 8.3.1.1, 9.2.1.2), as discussed in the SROCC (Meredith et al., 2019), observational studies coupled with modelling studies suggest that surface flux changes drive many observed near-surface salinity changes, on top of changes specific to polar regions. Advances in salinity observations (e.g., the Argo program (Riser et al., 2016); SMOS, Aquarius and SMAP (Supply et al., 2018; Vinogradova et al., 2019)), combined with process-studies (SPURS-1/2; (Lindstrom et al., 2015; SPURS-2 Planning Group 2015)) and methodological and numerical advances, have increased understanding of how subsurface salinity anomalies link to surface fluxes, and thus increase confidence that near-surface and subsurface salinity pattern changes since the 1950s are linked to changing surface freshwater fluxes (Zika et al., 2018; Cheng et al., 2020) with an additional contribution from changes in sea-ice and land-ice discharge at high latitudes (Haumann et al., 2016; Purich et al., 2018; Dukhovskoy et al., 2019a; Rye et al., 2020). There is therefore *medium confidence* in the processes linking surface fluxes to surface and subsurface salinity change.

Ocean circulation changes also affect salinity, largely on annual to decadal timescales (Du et al., 2019; Liu et al., 2019; Holliday et al., 2020). For instance, in the subpolar North Atlantic, increasing northward transport of "Atlantic waters" entering the subpolar gyre from the South have compensated the salinity decrease expected from increased Greenland meltwater flux since the early 1990s (Dukhovskoy et al., 2016, 2019b; Stendardo et al., 2020). After the mid-2010s the trend reversed towards a broad freshening, the largest in 120 years, in the North Atlantic (Holliday et al., 2020). The long term freshening in the Pacific Ocean has also been subject to decadal variability, such as a marked salinification since 2005 associated with increased surface fluxes (Li et al., 2019a). Local salinity anomalies forced by water cycle intensification can be weakened by rapid exchange between basins with opposing trends, such as by water-mass exchange in shallow wind-driven cells between the tropics and the subtropics (Levang and Schmitt, 2020). Similarly, eddy exchanges between neighbouring gyres can partly counterbalance decadal time scale long-term subpolar freshening and affect deep convection (Levang and Schmitt, 2020). There is *high confidence* that, at annual to decadal timescales, regional salinity changes are driven by ocean circulation change superimposed on longer term trends.

CMIP5 historical simulations have patterns similar to, but greater spatial variability than, observed estimates and correspondingly smaller amplitudes in the multi-model mean (Durack, 2015; Cheng et al., 2020; Silvy et al., 2020a). Section 3.5.2.1 reports, however, that the fidelity of ocean salinity simulation has improved in CMIP6, and near-surface and subsurface biases have been reduced (*medium confidence*), though the structure of the biases strongly reflects those of CMIP5. At regional scale, salinity biases are at least partially a result of inaccurate ocean dynamics (Levang and Schmitt, 2020). Despite the regional limitations, Section 3.5.2.2 assesses that at the global scale it is *extremely likely* that human influence has contributed to observed surface and subsurface salinity changes since the mid-20th century (strengthened from the *very likely* AR5 assessment).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The SROCC (Bindoff et al., 2019) assessed that projected salinity changes in the subsurface ocean reflect changes in the rates of formation of water masses or their newly formed properties. Additional consistent newer evidence based on CMIP5 and regional climate models confirms that 21st century projections adhere to the fresh gets fresher, salty gets saltier paradigm, through subduction of freshening high latitude waters into the ventilated water-masses in both hemispheres in the Pacific, Indian and Southern Ocean, especially the Arctic and upper Southern Ocean, and saltier subtropical and Mediterranean surface waters lead to saltier pycnoclines and North Atlantic mode water (Metzner et al., 2020; Parras-Berrocal et al., 2020; Silvy et al., 2020a; Soto-Navarro et al., 2020). Overall, projections confirm the SROCC assessment that fresh ocean regions will continue to get fresher and salty ocean regions will continue to get saltier in the 21st century (*medium confidence*).

9.2.2.3 Water Masses

Water masses refer to connected bodies of ocean water, formed at the ocean surface with identifiable properties (temperature, salinity, density, chemical tracers) resulting from the unique formation conditions of the overlying atmosphere and/or ice, before being transferred (subducted) to the deeper ocean below the surface turbulent layer. As water masses subduct, they ventilate the subsurface ocean, transferring characteristics acquired at the ocean surface to the subsurface. By integrating surface flux changes, water masses provide higher signal-to-noise ratios for detecting and monitoring climate change than surface fluxes (Bindoff and McDougall, 2000; Durack and Wijffels, 2010; Silvy et al., 2020b).

SubTropical Mode Waters (STMW) ventilate the main thermocline of the ocean at mid- to low-latitudes and have circulation timescales away from the surface of the order of years to decades. The SROCC (Bindoff et al., 2019) reported that warming in the subtropical gyres penetrates deeper than in other gyres, following the density surfaces in these gyres. Consistently, we assess that STMW have deepened worldwide, with greatest deepening in the Southern Hemisphere (*high confidence*) (Häkkinen et al., 2016; Desbruyères et al., 2017). Subsurface warming in the Northern Hemisphere STMW is larger than at the surface (Sugimoto et al., 2017) because they are formed in wintertime western boundary current extensions, where surface warming is larger than the global average (Section 9.2.1.1). Variability in STMW thickness or temperature has a large imprint on ocean heat content (Section 9.2.2.1) (Kolodziejczyk et al., 2019). STMW are observed to be freshening in the North Pacific and to be associated with increased salinity in the North Atlantic (Oka et al., 2017; Silvy et al., 2020a), with large decadal variability (Oka et al., 2019; Wu et al., 2020). Anthropogenic temperature and salinity changes in the STMW layer are projected to intensify in the future, with emergence from natural variability around 2020 to 2040 (Silvy et al., 2020a).

SubAntarctic Mode Water (SAMW) and Antarctic Intermediate Waters (AAIW) form at the Southern Ocean surface directly north of the Antarctic Circumpolar Current and ventilate the upper 1000 m of the Southern Hemisphere subtropics. The SROCC (Meredith et al., 2019) reported a freshening of these water masses between 1950 and 2018, and they are projected to have the largest subsurface temperature increase of the Southern Hemisphere oceans, along with a continued freshening, in the 21st century. The SROCC connected SAMW and AAIW to Southern Ocean temperature changes as the large Southern Ocean surface heat uptake is circulated and mixed along with these water masses (*high confidence*). Close to its formation region, SAMW is predominantly affected by air-sea flux changes, while further northward it is influenced by wind-forced changes (Meredith et al., 2019). New evidence shows that a change in SAMW heat content over the last decade is primarily attributable to its thickening (Kolodziejczyk et al., 2019). Over the past decade, the SAMW and AAIW volumes have changed by thickening of the lighter and thinning of the denser parts of SAMW and AAIW, leading to lightening of these ventilated ocean layers overall (Hong et al., 2020; Portela et al., 2020). Over the last decade, there is *limited evidence* of increased subduction of SAMW due to deepening mixed layers in the SAMW formation region (9.2.1.3) (Qu et al., 2020). Climate models from CMIP3 to CMIP5 generally simulated shallower and lighter SAMW and AAIW than is observed (Flato et al., 2013). New analysis of CMIP5 models suggests that the freshening of these water masses is one of the most prominent projected salinity changes in the world ocean, and that this freshening emerged from internal variability as early as the 1980–1990s (Silvy et al., 2020b).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Trends in North Atlantic Deep Water (NADW) are obscured by decadal variability (Rhein et al., 2013; Bindoff et al., 2019). The AR5 (Rhein et al., 2013) assessed that it is *very likely* that the temperature, salinity, and formation rate of the Upper NADW (formed by deep convection in the Labrador and Irminger Seas) is dominated by strong decadal variability related to the North Atlantic Oscillation (NAO) and it is *likely* that Lower NADW (formed in the Nordic Seas and supplied to the North Atlantic by deep overflows over the sills between Scotland and Greenland) cooled from 1955 to 2005. New insights from observations have emphasized the stability of the deep overflows associated with Lower NADW (Hansen et al., 2016; Jochumsen et al., 2017; Østerhus et al., 2019) and even slight warming in the Faroe Bank Channel (Hansen et al., 2016). As a result, the AR5 assessment that Lower NADW *likely* cooled between 1955 and 2005 is revised to: it is *likely* that any observed changes in temperature, salinity, and formation rate of the Lower NADW are dominated by decadal variability. For CMIP5 models it was shown that AMOC variability is linked to variability in NADW formation (Heuzé, 2017) and projected AMOC decline to decreased NADW formation (both Lower NADW and Upper NADW) (Heuzé et al., 2015). For CMIP6 models, projected AMOC decline is also associated with a decline in NADW formation (Reintges et al., 2017; Weijer et al., 2020). The link between AMOC and NADW formation appears insensitive to the large range in model bias in NADW water mass characteristics (Heuzé, 2017). Many models may overestimate deep water formation in the Labrador Sea, but at least one new model is consistent with recent OSNAP observations showing very weak overturning in the western subpolar gyre, where Labrador Sea Water is formed (Menary et al., 2020a). CMIP6 models show a reduced bias in NADW properties compared to CMIP5 models, but still feature varying locations of deep convection in the subpolar gyre: some convect only in the Labrador Sea (6/35 models), most in both the Labrador and Irminger Seas (26/35 models; as is observed), and some only in the Irminger Sea (3/35 models), but in general the area where deep convection takes place has expanded relative to CMIP5, which appears unrealistic (Heuzé, 2021). Models with most deep convection in the subpolar gyre feature the smallest bias in NADW characteristics, partly associated with NADW formed in the Nordic Seas (as observed) being largely unable to leave the area (Heuzé, 2021) due to inaccurate overflows (Danabasoglu et al., 2010; Deshayes et al., 2014; Wang et al., 2015b). Despite the wide range in model bias, it remains *very likely* that any long-term (multi-decadal or longer) decrease in AMOC is accompanied by a decline in NADW formation, associated with lighter densities in the northern North Atlantic and Arctic basins.

The SROCC (Meredith et al., 2019) assessed that the global volume of Antarctic Bottom Water (AABW) had decreased and warmed since the 1980s, most noticeably near Antarctica. The SROCC also noted freshening in the Indian and Pacific sectors of the Southern Ocean and a higher rate of freshening in the Indian Sector from the 2000s to 2010s than from the 1990s to 2000s (*low confidence*). Since the SROCC, freshening of Indian Ocean AABW from 1974 to 2016 has been revealed (Aoki et al., 2020). Additionally, interannual to decadal variability in AABW has been quantified to be larger than previously thought in terms of temperature, salinity and thickness, and in volume transport (Abrahamsen et al., 2019; Purkey et al., 2019b; Gordon et al., 2020; Silvano et al., 2020). Multidecadal-to-centennial modes of variability could have driven the observed trends of the lower cell over the past decades via the opening of a Weddell Sea polynya (Zhang et al., 2019b), although other studies find it contributed minimally to the observed abyssal warming (Zanowski et al., 2015; Zanowski and Hallberg, 2017). Therefore, there is *limited evidence* and *low agreement* in the role of open ocean polynyas in driving past decadal observed trends of AABW. Beyond variability, all observational, theoretical, and numerical evidence supports the SROCC assessment that formation and export of AABW will continue to decrease due to warming and freshening of surface source waters near the Antarctic continent. Consistent with Section 9.2.3.2, confidence in this assessment is increased to *medium confidence* compared to the SROCC.

Circumpolar Deep Water (CDW) lies in the Southern Ocean and forms by mixing of North Atlantic Deep Water and Antarctic Bottom Water (Talley, 2013). The SROCC (Meredith et al., 2019) assessed with *low confidence* that mean southward and upward CDW transport is linked to decadal wind variability (Section 9.2.3.2), and that CDW has warmed south of the Antarctic Circumpolar Current (ACC) in the past decades. New evidence reinforces the SROCC assessment: changes in Southern Ocean wind stress have been confirmed to drive variability and increase the large-scale southward CDW transport (Waugh et al., 2019). In addition, growing evidence suggests that the upper ocean stratification increase in the subpolar Southern Ocean since the 1970s (Section 9.2.1.3) has reduced the volume of CDW that is mixed to the surface, causing subsurface CDW warming (Bronselaer et al., 2020; Haumann et al., 2020; Jeong et al., 2020;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Moorman et al., 2020). Large regions of the Antarctic shelves are currently isolated from warm CDW (Thompson et al., 2018; Jourdain et al., 2020). The SROCC (Meredith et al., 2019) assessed that subsurface warming extends close to Antarctica and has co-occurred with shoaling of the CDW since the 1980s, influencing the continental shelf most in the Amundsen-Bellingshausen Seas, Wilkes Land, and the Antarctic Peninsula. New evidence since the SROCC reinforces confidence in the importance of the role of winds in transporting heat associated with CDW to continental shelves and ice cavities in the Amundsen-Bellingshausen Seas (Dotto et al., 2019) and via variable small-scale undercurrents to the Shirase Glacier Tongue in East Antarctica (Hirano et al., 2020; Kusahara et al., 2021). There is *limited evidence* that increased greenhouse gas forcing has caused a slight mean change of the local winds from 1920-2018 facilitating CDW heat intrusion onto the Amundsen-Bellingshausen continental shelf and ice-shelf melt (Holland et al., 2019). Multiple lines of observational, numerical, theoretical, and paleo evidence provide *high confidence* that changes in wind pattern (Spence et al., 2014; Dotto et al., 2019; Holland et al., 2019), increased ice-shelf melt (Golledge et al., 2019a; Moorman et al., 2020), reduction in sea-ice production (Timmermann and Hellmer, 2013; Obase et al., 2017), and eddies (Stewart and Thompson, 2015; Thompson et al., 2018) can facilitate access of CDW to the sub-ice-shelf cavities (9.4.2.1). However, there is *low confidence* in the quantitification, importance and the ability of present models, especially at coarse resolution, to project changes in each of these processes (9.4.2.2). Some studies have projected a possible shift from cold to warm sub-ice shelf cavities causing a sudden flush of warm water underneath ice shelves, but there is *low confidence* both in the driving processes and the threshold to trigger the shift (Box 9.4) (Hellmer et al., 2012, 2017; Silvano et al., 2018; Hazel and Stewart, 2020).

9.2.3 Regional Ocean Circulation

9.2.3.1 Atlantic Meridional Overturning Circulation

The Atlantic meridional overturning circulation (AMOC) is the main overturning current system in the South and North Atlantic Oceans. It transports warm upper-ocean water northwards, and cold, deep water southwards, as part of the global ocean circulation system (Section 2.3.3.4.1). AMOC changes influence global ocean heat content and transport (Section 9.2.2.1); global ocean anthropogenic carbon uptake changes and climate sensitivity (Cross-Chapter Box 5.3); and dynamical sea level (Section 9.2.4). Since the AR5/SROCC, confidence in modelled and reconstructed AMOC has decreased due to new observations and model disagreement. Confidence in modelled AMOC evolution during the 20th century, the magnitude of 21st century AMOC decline, and the possibility of an abrupt collapse before 2100 have been revisited.

The AR5 (Flato et al., 2013) found that the mean AMOC strength in CMIP5 models ranges from 15 to 30 Sv for the historical period. The multi-model mean overturning at 26°N in CMIP5 and CMIP6 is comparable to the RAPID measurements (Reintges et al., 2017), but the inter-model spread in CMIP6 is as large (10-31 Sv) as in CMIP5 ((Weijer et al., 2020); Section 3.5.4). Biases in simulations of the present day AMOC and associated deep convection in the subpolar gyre and Nordic Seas were large in CMIP5 models with many models exhibiting ocean convection that is too deep, over too large an area, too far south and occurring too frequently (Heuzé, 2017) (Section 9.2.1.3; Figure 9.5) related to biases in sea-ice extent, overflows, and freshwater forcing (Deshayes et al., 2014; Wang, Legg and Hallberg, 2015). As a result, the AMOC in CMIP5 was nearly always too shallow, with too weak a temperature contrast between the northward and southward flowing branches. Deep convection errors are still large in CMIP6 and the shallow bias in AMOC persists (Weijer et al., 2020; Heuzé, 2021). Since the AR5, there is emerging evidence that enhancing horizontal resolution can reduce longstanding climate model biases in AMOC strength, where the magnitude and profile of northward heat transport at 26°N become more comparable to observations (Chassignet et al., 2020; Roberts et al., 2020a). The sensitivity of the AMOC to ocean resolution, however, is model-dependent and can be positive as well as negative (Roberts et al., 2020b). An increase in AMOC strength at 26°N with higher resolution in the ocean component has been associated with too strong (deep) convection in the subpolar gyre and too deep winter mixed layers (Jackson et al., 2020a), which occurs in most CMIP6 models that are unable to overflow deep water formed in the Nordic Seas across the Greenland-Iceland-Scotland Ridge. Thus models with a correct AMOC strength may do so by compensating a lack of deep water outflow from the Nordic Seas through too much deep convection and deep-water formation in the Labrador and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Irminger Seas (Heuzé, 2021).

Models and paleo-reconstructions have often assumed a close relation between the AMOC and deep convection in the Labrador Sea, and Labrador Sea convection variability has been interpreted as connecting to AMOC variability. Observational studies have been inconclusive on whether this relation exists (Buckley and Marshall, 2016). New insight from observed overturning in the eastern and western subpolar gyre in the North Atlantic in OSNAP (Lozier et al., 2019; Petit et al., 2020) reveal that 15.6±3.1Sv takes place north of the OSNAP array between Greenland and Scotland, with only 2.1±0.9 Sv of overturning occurring across the Labrador Sea as found with the OSNAP 53ºN array spanning the mouth, explicitly questioning the validity of the Labrador Sea convection-AMOC link (Lozier et al., 2019). Although their results are derived from only the first 21 months of data of monitoring since 2014, hydrographic observations during 1990-1997 previously found small overturning (1-2 Sv) in the Labrador Sea (Pickart and Spall, 2007). On the other hand, previous estimates of Labrador Sea Water formation (obtained with different techniques) suggest larger overturning (Haine et al., 2008). Part of this controversy could be explained if a large fraction of newly formed Labrador Sea Water is not exported from the Labrador Sea. The OSNAP observations are supported by previous hydrographic measurements in showing strong east-west symmetry in isopycnal slope in the Labrador Sea in periods of both strong and weak convection, implying compensating northward and southward transport above and below the potential density surface that separates the upper and lower overturning limbs (Lozier et al., 2019), despite large deep convection variability (Yashayaev, 2007; Yashayaev and Loder, 2016). New observations of deep winter mixing in the Irminger Basin (de Jong et al., 2018; Josey et al., 2019) support the assertion that the Irminger Sea, in addition to the Nordic Seas (Chafik and Rossby, 2019), are the main sources of overturning in the eastern subpolar gyre, consistent with OSNAP (Petit et al., 2020). It is unclear to what extent models are in disagreement with this view of overturning in the subpolar gyre, as a direct comparison with OSNAP in terms of partitioning the overturning in a western and eastern part is lacking for most models, with a notable exception (Menary et al., 2020a). The analysis of water mass formation in CMIP6 models (Heuzé, 2021); the analysis between Labrador Sea water formation and AMOC in a suite of ocean-only models (Danabasoglu et al., 2014); the fact that when the OSNAP observing system design was tested in an eddy-permitting ocean model, almost equal amounts of overturning in the western and eastern subpolar gyre were found (Lozier et al., 2017), give rise to considerable uncertainty over the models' veracity in simulating the overturning partitioning between east and west and the role of various drivers of AMOC variability. Disagreement between models and OSNAP observations may decrease in higher-resolution models (Menary et al., 2020a). In summary, multiple lines of evidence provide *medium agreement* between models and observations on drivers of change and variability in the AMOC and in particular the role of Labrador Sea deep convection in constituting AMOC variability.

The AMOC is a potential driver of Atlantic Multidecadal Variability (AMV), but there is new evidence that anthropogenic aerosol changes have contributed to observed AMV changes, and that underestimation of the magnitude and duration of AMV changesin CMIP5 is tempered in CMIP6 (Section 3.7.7, Annex IV.2.7). Comparison of observed AMOC variability at the RAPID section with modelled variability reveals that CMIP5 models appear to largely underestimate the interannual and decadal timescale variability (Roberts et al., 2014; Yan et al., 2018), and similar results are found when analysing CMIP6 models (Section 3.5.4.1). By underestimating the multi-decadal AMOC-AMV link and other low-frequency AMOC variability climate models also underestimate internal variability in subpolar SSTs that feedback on the North Atlantic Oscillation (NAO), causing the NAO to lack variability on multidecadal timescales (Kim et al., 2018). Despite the role of the AMOC in generating AMV through subsurface temperatures in antiphase with SST and downward heat fluxes into the ocean that anticorrelate with SSTs (Zhang et al., 2019d), it is generally accepted that AMOC forcing of SST variability exists alongside stochastic wind forcing and external forcing by aerosols (Bellomo et al., 2018; Haustein et al., 2019; O'Reilly et al., 2019; Wills et al., 2019).

The SROCC (Collins et al., 2019) assessed that in situ observations (2004–2017) and sea surface temperature reconstructions indicate that the AMOC has weakened relative to 1850–1900 (*medium confidence*). However, the SROCC also assessed that there is insufficient data to quantify the magnitude of the weakening, or to properly attribute it to anthropogenic forcing, due to the limited length of the observational record. Here, this assessment is adjusted to *low confidence*in the weakening as also discussed in Sections 2.3.3.4.1 and 3.5.4.1. The CMIP5 multi-model mean showed no 20th century trend in the AMOC

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Cheng et al., 2013). The CMIP6 multi-model mean even slightly opposes the reconstructed decline due to a strong increase in the 1940-1985 period (Menary et al., 2020c; Weijer et al., 2020), thought to be in response to aerosol forcing (Section 3.5.4.1), followed by a smaller decline since the nineties. Also, agreement between different proxy-based reconstructions is weak in many details (Moffa-Sánchez et al., 2019) and questions can be raised regarding various proxies used in reconstructions (Section 2.3.3.4.1). For instance, SST-based proxies can be influenced by atmospheric and other processes acting on different timescales (Moffa-Sánchez et al., 2019; Jackson and Wood, 2020). In addition, many proxies are indirect and based on AMOC-related processes assumed to be similar as found in models, such as the link between AMOC and Labrador Sea convection, which has been questioned recently (see above). In addition, the subpolar gyre from which many AMOC-proxies are taken may vary independently of the AMOC with rather similar patterns in SST and ocean heat content driven by wind variability (Williams et al., 2014; Piecuch et al., 2017). Finally, a new dynamic reconstruction of the Atlantic inflow to the Nordic Seas suggest no slowdown over the past 70-100 years (Rossby et al., 2020), in contrast to a new compilation of proxy reconstructions which suggests that the AMOC is presently in its weakest state in the last millennium (Caesar et al., 2021), reinforcing the evidence that motivated the previous SROCC assessment. Section 3.5.4.1 also questions the veracity of the models' forced AMOC response during the twentieth century. Given the large discrepancy between modelled and reconstructed AMOC in the twentieth century and the uncertainty over the realism of the 20th century modelled AMOC response (Section 3.5.4.1), we have *low confidence* in both.

The strength of the AMOC has been measured directly since 2004 using the RAPID Array (Smeed et al., 2018) (Section 2.3.3.4.1). RAPID-based estimates show a large amount of variability compared to CMIP models (Roberts et al., 2014). Observed changes since 2004 are too short for the evaluation of a long-term trend given the decadal scale internal variability (Section 2.3.3.4.1). Nevertheless, Smeed et al. (2018) argue that between 2007 and 2011 the AMOC shifted to a state of reduced overturning; decreasing from 18.8 Sv between 2004 and 2008 to 16.1 Sv after 2008. A shift in AMOC strength of this magnitude is not captured by CMIP5 and CMIP6 models, which generally underestimate interannual to decadal AMOC variability (Section 3.5.4.1). Additional evidence since SROCC also raises the inconsistency between the RAPID weakening in the 3000-5000 m depth range and the relative constancy of deep overflows from the Arctic (Østerhus et al., 2019), implying that the recent decrease in AMOC at 26.5ºN (Smeed et al., 2018) is not caused by overflow weakening or reduced overturning in the Nordic Seas, although the weakening occurred almost exclusively in the 3000 – 5000 m depth range associated with a reduction of Lower NADW (Section 9.2.2.3). It is unclear what causes a weakening of the deepest limb of the AMOC at 26.5ºN, if the main sources for this flow farther north remain constant. Various estimates of AMOC and associated heat transport suggest an increase since the 1940s with a subsequent decrease since the 1990s (Section 2.3.3.4.1), supported by ocean reanalysis (Jackson et al., 2019), forced ocean model simulations (Robson et al., 2012; Danabasoglu et al., 2016) and CMIP6 simulations (Menary et al., 2020b). This suggests that the observed AMOC-shift between 2007 and 2011 may be part of a longer-term decrease (*medium confidence*), which has been attributed to be part of multiannual variability (Rhein et al., 2019).

[START FIGURE 9.10 HERE]

Figure 9.10: AMOC strength in simulations and sensitivity to resolution and forcing. (Top left) AMOC magnitude in PMIP experiments. (Top right) Time series of AMOC from CMIP5 and CMIP6 based on (Menary et al., 2020c). (Bottom left) Percent change in AMOC strength per year at different resolutions over the 1950-2050 period with colours for model families (Roberts et al., 2020b). (Bottom right) A compilation (Jackson and Wood, 2018) of percentage changes in the simulated AMOC after applying an additional freshwater flux in the subpolar North Atlantic at the surface for a limited time (de Vries and Weber, 2005; Stouffer et al., 2006; Yin and Stouffer, 2007; Jackson, 2013; Liu and Liu, 2013; Jackson and Wood, 2018; Haskins et al., 2019). Symbols indicate whether the AMOC recovers within 200 years (circles), is starting to recover (upwards arrow) or does not recover within 200 years (downwards arrow). Symbol size indicates rate of freshwater input. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.10 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The SROCC (Collins et al., 2019) found that the AMOC will *very likely* weaken over the 21st century. In CMIP6 projections, the modelled decline starting in the 1990s continues in all future projections, almost independent of the forcing scenario until about 2060, after which low emission scenarios show stabilization, while high-emission scenarios continue to exhibit AMOC decline (Figure 9.10) (Menary et al., 2020b, Weijer et al., 2020).Despite differences in overall AMOC strength, location and latitude of deep convection, sea-ice and SST bias and representation of deep overflows, the model projections are qualitatively similar. This agreement suggests that AMOC decline may be governed by large-scale constraints independent of the details of the models. In theoretical models of the thermohaline circulation, the circulation strength is proportional to a density or pressure difference between the subpolar North Atlantic and subtropical South Atlantic (Kuhlbrodt et al., 2007; Weijer et al., 2019). In all models, the north-south pressure gradient decreases in the 21st century, as subpolar waters warm faster than subtropical waters and an enhanced hydrological cycle drives freshening at subpolar latitudes, while subtropical latitudes feature more evaporation and salinification (Section 9.2.1). As a result, surface waters at subpolar latitudes become more buoyant and more stable, so that deep water formation driving the AMOC declines (Section 9.2.1.3). Projected AMOC decline by 2100 ranges from 24% (4-46%) in SSP1-2.6 to 39% (17-55%) in SSP5-8.5 (*medium confidence*; Section 4.3.2.3). Note that these ranges are based on ensemble means of individual models, largely smoothing out internal variability. If single realisations are considered the ranges become larger, lowering especially the low end of the range (Section 4.3.2.3). In summary, it is *very likely* that AMOC will decline in the 21st century, but there is *low confidence* in the models' projected timing and magnitude. In addition, freshwater from the melting of the Greenland ice sheet (Sections 9.4.1.3, 9.4.1.4) could further enhance the future weakening of the AMOC in the 21st century (Collins et al., 2019; Golledge et al., 2019).

Both the AR5 (Collins et al., 2013) and the SROCC (Collins et al., 2019) assessed that an abrupt collapse of the AMOC before 2100 was *very unlikely*, but the SROCC added that by 2300 an AMOC collapse was *as likely as not* for high-emission scenarios. The SROCC also assessed that model-bias may considerably affect the sensitivity of the modelled AMOC to freshwater forcing. Tuning towards stability and model biases (Valdes, 2011; Liu et al., 2017; Mecking et al., 2017; Weijer et al., 2019) provides CMIP models a tendency toward unrealistic stability (*medium confidence*). By correcting for existing salinity biases, Liu et al. (2017) demonstrated that AMOC behaviour may change dramatically on centennial to millennial timescales and that the probability of a collapsed state increases. None of the CMIP6 models features an abrupt AMOC collapse in the 21st century, but they neglect meltwater release from the Greenland ice sheet and a recent process study reveals that a collapse of the AMOC can be induced even by small-amplitude changes in freshwater forcing (Lohmann and Ditlevsen, 2021). As a result, we change the assessment of an abrupt collapse before 2100 to *medium confidence* that it will not occur.

9.2.3.2 Southern Ocean

The changing Southern Ocean circulation system exerts a strong influence on the global climate by modulating (i) global ocean heat content (Section 9.2.2.1); (ii) global ocean anthropogenic carbon uptake (Cross-chapter Box 5.3); global ocean overturning circulation (Section 9.2.3.1); climate sensitivity (Section 7.4.4 and Cross-chapter Box 5.3); (iii) sea level through basal melt of ice shelves (9.4.2); and Southern Hemisphere sea-ice cover (Section 9.3.2).

The SROCC (Meredith et al., 2019) had *low confidence* in all CMIP5-based model projections due to their inability to explicitly resolve eddy processes and their inability to properly consider future meltwater change from the Antarctic Ice Sheet. These limitations of climate models to represent the Southern Ocean persist due to most CMIP6 models still using parameterized mesoscale eddy processes that are limited in projecting the future response of the horizontal and vertical circulation under climate warming, and due to the continued absence of active ice shelf and ice sheet coupling in the CMIP6 model suite, therefore ignoring basal meltwater and calving feedback on the circulation (Meredith et al., 2019). In addition, two important limitations of CMIP6 models of the Southern Ocean involve processes that were not assessed in the SROCC. First, the poor representation of dense overflows causes most of the Antarctic Bottom Water (AABW) to be formed by spurious open ocean convection rather than by dense overflows from the Antarctic continental

ACCEPTED VERSION SUBJECT TO FINAL EDITING

shelves that feed the lower overturning cell (Snow et al., 2015; Dufour et al., 2017; Heuzé, 2021). Second, Antarctic continental shelf waters are poorly simulated because potentially important controlling mechanisms tend to be too small and transient to observe and resolve in CMIP ocean models. These small processes include the heterogeneity of observed sub-ice shelf melt with warm water driving narrow basal channels that cut underneath the ice (Drews, 2015; Alley et al., 2016; Marsh et al., 2016; Milillo et al., 2019); eddies and tides (Stewart et al., 2018; Jourdain et al., 2019; Hausmann et al., 2020), which can drive Circumpolar Deep Water (CDW) onto the continental shelves or dynamically increase melting (Section 9.2.3.6); and feedback mechanisms between ocean, atmosphere and cryosphere that can weaken or amplify initial perturbations (Donat-Magnin et al., 2017; Spence et al., 2017; Turner et al., 2017; Silvano et al., 2018; Webber et al., 2019; Hazel and Stewart, 2020). In addition, the Southern Ocean in CMIP5 and CMIP6 models exhibit surface temperature biases (Section 9.2.1.1), which have been linked in CMIP5 model to errors in atmospheric model cloud-related short-wave radiation (Hyder et al., 2018) and are somewhat improved in HighResMIP models (Figure 9.3). In summary, there is *high confidence* that future change in the subpolar Southern Ocean region including sea-ice cover and ocean temperature change on Antarctic continental shelves depends on feedback mechanisms involving the ocean, atmosphere and cryosphere that are poorly understood and not represented in the current generation of climate models. This results in large uncertainty and *low confidence* in the future sea-ice cover (Section 9.3.2) and in ocean temperature change on the Antarctic continental shelf (Section 9.4.2.3).

Despite these challenges, the CMIP6 ensemble does represent the main Southern Ocean circulation characteristics; the simulated Antarctic Circumpolar Current (ACC) transport is generally lower than observation-based values but consistent when considering ensemble spread and the inter-model spread in ACC transport has greatly reduced from previous generations of climate models from CMIP3 to CMIP6 (Beadling et al., 2019, 2020). The structure (but not the magnitude) of the two-cell zonally-averaged overturning is captured by most CMIP6 models (Russell et al., 2018; Beadling et al., 2019). In addition, while issues remain, CMIP6 climate models show clear improvements in their representation of AABW compared to CMIP5: several models correctly represent or parameterise Antarctic shelf processes, fewer models exhibit Southern Ocean deep convection, bottom density biases are reduced, and abyssal overturning is more realistic (Heuzé, 2021). In terms of atmospheric wind forcing, CMIP6 models show an improvement compared to CMIP5 models with an overall reduction in the equatorward bias of the annual mean westerly jet from 1.9° in CMIP5 to 0.4° in CMIP6, but in contrast they show no such overall improvements for their representation of the Amundsen Sea Low (Bracegirdle et al., 2020; Lyu et al., 2020a), which can be critical in driving variability of water-masses on the Antarctic continental shelf in west Antarctica, the Weddell Sea or the Ross Sea(Holland et al., 2019; Silvano et al., 2020).

The SROCC (Meredith et al., 2019) established that while trends in the atmospheric forcing of the Southern Ocean have been dominated by a strengthening of the southern hemisphere westerly winds in recent decades, there is *medium confidence* that ACC transport is weakly sensitive to changes in winds. It also reported that instead of increasing the mean ACC transport, additional energy input associated with increased wind stress cascades into the eddy field (*medium confidence*). In contrast with the AR5 assessment (Rhein et al., 2013), the SROCC evaluated that it was *unlikely* that there has been a net southward migration of the mean ACC position over the past 20 years. There is no additional evidence to revisit the SROCC assessment on wind sensitivity. However, new evidence does suggest that air-sea buoyancy forcing associated with idealised $4xCO_2$ forcing leads to an increase in ACC transport (Shi et al., 2020) (*limited evidence*). The SROCC noted that if the general strengthening in westerly winds is sustained, then it is *very likely* that the eddy field will continue to increase in intensity, and that is *likely* that the mean position and strength of the ACC will remain only weakly sensitive to winds. In the future, the strength of the Southern Hemisphere westerly wind jet results from a competition between decrease due to ozone hole recovery and increase due to increased radiative forcing (Section 4.3.3.1). This competition results in an increased atmospheric jet by 2100 compared to present day under SSP2-4.5, SSP3-7.0, and SSP5-8.5, but a decreased jet by 2100 under SSP1-2.6 (Bracegirdle et al., 2020). There is little inter-model spread in the CMIP6 future response of the atmospheric westerly jet, providing *high confidence* in this assessment (in contrast, CMIP6 models show no consistency in their future projection of easterly wind change along the Antarctic continental shelf break) (Bracegirdle et al., 2020). Paleo-oceanographic evidence suggests that ACC flow through Drake Passage was consistently stronger during warm intervals of the past (both during interstadials and interglacials), but with

ACCEPTED VERSION
SUBJECT TO FINAL EDITING

relatively little change and no consensus on the sign of change in other regions (Lamy et al., 2015; Toyos et al., 2020). In summary, additional evidence since the SROCC confirms that there is *medium confidence* that the ACC has been weakly sensitive to Southern Hemisphere atmospheric jet increase in the past decades. New evidence since the SROCC suggests that there is *high confidence* that the Southern Hemisphere atmospheric jet will increase in the 21st century for all scenarios (except for SSP1-1.9 and SSP1-2.6; Section 4.3.3.1) with a greater increase for larger radiative forcing. An increase in westerly winds will *very likely* force an increase of the eddy field in the ACC, and while there is *medium confidence* that the ACC is weakly sensitive to wind change, new advances since the SROCC provide *limited evidence* that the ACC transport will nevertheless increase in response to wind and buoyancy fluxes.

For the upper cell overturning circulation, the SROCC concluded that its transport has experienced significant inter-decadal variability in response to wind forcing since the 1990s, and that there is *low confidence* in the assessments of a long-term increase in upper ocean overturning. Consistent with the SROCC, the importance of both eddy processes and winds in driving long-term change and variability have been reinforced, with a potential fast wind response partially counteracted by a slower eddy response (Doddridge et al., 2019; Waugh et al., 2019; Stewart et al., 2020). Eddy parameterizations affect the strength of overturning, its sensitivity to winds and the ACC transport (Mak et al., 2017). Even in eddy resolving simulations sub-gridscale dissipation affects the overturning and ACC (Pearson et al., 2017). In addition, there has been progress in understanding the importance of Antarctic Ice Shelf meltwater and sea-ice, in driving the observed changes in the near surface and in the upper overturning cell over the past decades, on top of changes induced by winds and eddies (Bronselaer et al., 2020; Haumann et al., 2020; Jeong et al., 2020; Rye et al., 2020). In particular, increased stratification caused by increased freshwater flux to the surface ocean (Section 9.2.1.3) can cause a shoaling and warming of the Circumpolar Deep Water layer, and create a positive feedback enhancing basal melt of the Antarctic Ice Sheet (Section 9.4.2.1) (Bronselaer et al., 2018; Golledge et al., 2019a; Schloesser et al., 2019; Sadai et al., 2020). There is *medium confidence* in the existence of this feedback mechanism but *low agreement* on the magnitude of the feedback. The SROCC reported that CMIP5 models project that the overall transport of upper ocean overturning cell will increase by up to 20% in the 21st century, and no new studies alter that assessment.

For the lower cell overturning circulation, the SROCC assessed that a slowdown of its transport is consistent with the observed decrease in volume (*medium confidence*) of AABW in the global ocean (Section 9.2.2.3). Additional evidence since the SROCC, strengthens confidence that increased glacial meltwater flux will reduce the density of bottom waters during the 21st century, eventually reaching a point where deep convection will be curtailed and shelf water will become too buoyant to sink to the ocean interior, thereby slowing the lower cell overturning circulation (Bronselaer et al., 2018; Golledge et al., 2019a; Lago and England, 2019; Moorman et al., 2020). While such changes are consistent with the observed freshening and volume decrease of the AABW layer reported in the SROCC, as discussed in Section 9.2.2.3, new observation-based studies have highlighted how the lower cell overturning can episodically increase as a response to climate anomalies, temporally counteracting the tendency for melt to reduce AABW formation (Abrahamsen et al., 2019; Castagno et al., 2019; Gordon et al., 2020; Silvano et al., 2020). In addition, while the opening of open ocean polynyas can affect the lower cell on decadal to centennial time-scales, there is *limited evidence* and *low agreement* in the role of open ocean polynyas in driving observed trends of the lower cell in the last decade (Section 9.2.2.3). Based on CMIP5 models, the SROCC reported with *low confidence* that formation and export of AABW associated with the lower overturning cell will decrease in the 21st century, and there is no new evidence to revisit that assessment from climate models. However, additional paleo evidence from marine sediments suggest that AABW formation/ventilation was vulnerable to freshwater fluxes during past interglacials (Hayes et al., 2014; Huang et al., 2020; Turney et al., 2020) and that AABW formation was strongly reduced (Skinner et al., 2010; Gottschalk et al., 2016; Jaccard et al., 2016) or possibly totally curtailed (Huang et al., 2020) during the LGM and transient cold intervals of MIS 2 & 3. Specifically, sedimentary reconstructions show a transient reduction in AABW ventilation in the Atlantic sector of the Southern Ocean during MIS5e, which is assessed to have been warmer than modern climate (Thomas et al., 2020). However, long multi-centennial or millennial model runs under higher-than-pre-industrial CO_2 concentrations show that after 500 -1000 years, ventilation in the Southern Ocean resumes, and even possibly overshoots with enhanced convection in the Weddell and Ross seas leading to enhanced bottom water ventilation globally (Yamamoto et al., 2015; Frölicher et al., 2020). AABW

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ventilation increased at the onset of the last deglacial transition, promoting the release of previously sequestered CO_2 to the atmosphere on centennial to millennial timescales (Bauska et al., 2016; Jaccard et al., 2016; Rae et al., 2018), concomitant with a southward shift of the SH westerly wind belt (Denton et al., 2010; Jaccard et al., 2016) and reduced sea-ice cover (Ferrari et al., 2014; Stein et al., 2020). In summary, the combination of observational, numerical and paleoclimate evidence provides us with *medium confidence* that the lower cell will continue decreasing in the 21st century as a result of increased basal melt from the Antarctic Ice Sheet.

9.2.3.3 Tropical Oceans

The tropics are a tightly coupled ocean-atmosphere system with tightly interconnected basins (Cai et al., 2019). The zonal atmospheric Walker Circulation and the Indonesian Throughflow (ITF, Figure 9.11) are key connections between the Pacific and Indian Oceans, and variations in the Walker and Hadley Circulations are tightly linked to the tropical Pacific SST and currents. The tropics have a profound influence on the climate system through the multiple modes of variability they host, which have widespread global influence at seasonal to annual timescale (Annex IV).

The effect of tropical modes of variability on climate and their long-term changes are reviewed in detail in Annex IV, while changes to the tropical ocean are assessed throughout the report and briefly summarized here. Section 2.4 concludes that a sustained shift beyond multi-centennial variability has not been observed for ENSO (*medium confidence*) and that there is *limited evidence* and *limited agreement* about the long-term behaviour of other tropical modes. Section 3.7 assesses with *high confidence* that human influence has not affected the principal tropical modes of interannual climate variability and their associated regional teleconnections beyond the range of internal variability. Section 4.3.3.2 assesses with *medium confidence* that there is no consensus from models for a systematic change in the amplitude of El Niño–Southern Oscillation sea surface temperature variability over the 21st century. The related change in tropical SSTs is covered in Section 9.2.1.1. The projected changes in SST have implications for marine heat wave characteristics, which are assessed in Box 9.2. SST changes in the tropics are related to changes in the atmospheric circulation, including surface equatorial easterly trade winds and Walker Circulation (Section 4.5.3.2), and the weakening Indonesian Throughflow and strengthening Agulhas Extension and leakage (Section 9.2.3.4). Weakening trade winds under climate change (Vecchi and Soden, 2007) will tend to decrease upwelling, along isopycnals in the eastern Pacific and diapycnal upwelling in the central Pacific and thus the meridional temperature gradients that drive Tropical Instability Waves (Terada et al., 2020), along with a weakening, flattening and shoaling of the tropical thermocline and equatorial undercurrent (Luo and Rothstein, 2011). A weak or absent Equatorial Undercurrent (Kuntz and Schrag, 2020) and a too diffuse and incorrectly sloped tropical thermocline (Zhu et al., 2020) remain issues in most CMIP6 models. In summary, while future changes in tropical modes of variability remain unclear, change in atmospheric and ocean circulation will drive continued change in tropical ocean temperature in the 21st century (*medium confidence*), with part of the region experiencing drastic marine heat wave conditions (*high confidence*).

9.2.3.4 Gyres, Western Boundary Currents, and Inter-Basin Exchanges

The AR5 (Rhein et al., 2013) assessed with *medium* to *high confidence* that the North Pacific subpolar gyre, the South Pacific subtropical gyre, and the subtropical cells have intensified. They also reported that the North Pacific subtropical gyre had expanded since the 1990s, and that overall the changes in gyre systems were *likely* predominantly due to interannual-to-decadal variability. The SROCC (Meredith et al., 2019) complemented the AR5 assessment by reporting that the polar Beaufort Gyre in the Arctic expanded to the northwest between 2003 and 2014, contemporaneous with changes in its freshwater accumulation and alterations in wind forcing. Consistent with the reported change over the gyres, both the AR5 and the SROCC (Bindoff et al., 2019; Collins et al., 2019) reported that Western Boundary Currents (WBCs) have intensified (Figure 9.11), and expanded poleward, except for the Gulf Stream and the Kuroshio. Section 2.3.3.4 provides an overall assessment of gyres and WBCs including an assessment of change from paleoclimate archives. Section 2.3.3.4 assesses that while WBC strength is highly variable at multidecadal

ACCEPTED VERSION SUBJECT TO FINAL EDITING

scale (*high confidence*), WBCs and subtropical gyres have shifted poleward since 1993 (*medium confidence*), at a rate on the order of 0.04-0.1 degree per decade during 1993-2018. Figure 9.11 shows that CMIP5 and CMIP6 models agree in projecting a weaker Gulf Stream and Gulf Stream Extension, while the Kuroshio changes less (Sen Gupta et al., 2016).

Although the observed wind stress curl shows systematic poleward shift in each basin as a result of anthropogenic warming (Section 2.3.1.4) (Chen and Wu, 2012; Wu et al., 2012; Zhai et al., 2014), which has caused a systematic shift of the WBCs and subtropical gyres since 1993 (Wu et al., 2012; Yang et al., 2016b, 2020), the response of current strength is more complex and inconsistent across regions (Sloyan and O'Kane, 2015; Wang et al., 2016c; Elipot and Beal, 2018; McCarthy et al., 2018; Wang and Wu, 2018; Dong et al., 2019). The strength of WBCs and gyres exhibit inconsistent responses because they are not only dependent on wind stress forcing, but multi-scale interaction and air-sea interaction have an important role in their long-term trends and variability (Zhang et al., 2020). Observed changes in gyre circulation are dominated by interannual and decadal modes of variability globally (Qiu and Chen, 2012; Melzer and Subrahmanyam, 2017; McCarthy et al., 2018; Hu et al., 2020). The North Atlantic subpolar gyre is strongly modulated by variability associated with the NAO and AMV (Robson et al., 2016) (Annex IV). Subpolar gyre systems can change abruptly due to a positive feedback between convective mixing and salinity transport (Born et al., 2013, 2016) and air-sea interaction (Moffa-Sánchez et al., 2014; Moreno-Chamarro et al., 2017) within the gyre. In the Arctic, both the Beaufort gyre and mesoscale eddies strengthened between 2003 and 2014 (Armitage et al., 2017), which might be partly due to increased wind stress (Oldenburg et al., 2018b) or reduced sea-ice thickness and changes in sea-ice pack morphology (van der Linden et al., 2019). Presently, there is *limited evidence* in attributing causality to these changes for any of the proposed mechanisms. In the North Pacific, there has been an increasing trend in the Alaska Gyre from 1993 to 2017 (Cummins and Masson, 2018), which might be attributed to PDO (Hristova et al., 2019) (*low confidence*). In the Southern Ocean, *limited evidence* indicates that the subpolar gyres respond to Southern Hemisphere atmospheric modes of variability at interannual time-scale (Armitage et al., 2018; Dotto et al., 2018).

All climate models reproduce WBCs and gyres, but eddy-present or eddy-rich models (roughly 10-25 km and ~10 km resolution, respectively) represent these currents more realistically than eddy-parameterized models (Small et al., 2014a; Griffies et al., 2015; Chassignet et al., 2017; Hewitt et al., 2017; Roberts et al., 2018; Chassignet et al., 2020; Hewitt et al., 2020) (*very high confidence*). Compared to observations or to eddy-present and eddy-rich models, the eddy-parameterized models from CMIP5 and CMIP6 simulate weaker and wider WBCs as well as less realistic locations of subtropical and subpolar gyre boundaries (Figure 9.11). Increased resolution not only admits mesoscale eddies, but also improves simulation of the strength and position of WBCs such as the Kuroshio Current, Gulf Stream, and East Australian Current (Sasaki et al., 2004; Chassignet and Marshall, 2008; Delworth et al., 2012; Yu et al., 2012; Small et al., 2014b; Haarsma et al., 2016; Chassignet et al., 2017, 2020; Hewitt et al., 2020) (*very high confidence*). Improved boundary current location relates to improved recirculation regions (Jayne et al., 2009), mean path and variability and existence of multiple stable paths (Qiu et al., 2005; Delman et al., 2015), air-sea fluxes (Small et al., 2014a), and related coastal weather patterns (Kaspi and Schneider, 2011). The wind-current feedback, implemented by considering relative velocity of currents and wind, realistically dampens mesoscale eddies and WBCs, through mesoscale air-sea interaction (Ma et al., 2016; Renault et al., 2016, 2019), even though sub-mesoscale wind-current damping feedback is missing in these models (Zhang et al., 2016c) (*medium confidence*). As eddies potentially play a role in determining the strength of gyre circulations and their low-frequency variability (Fox-Kemper and Pedlosky, 2004; Berloff et al., 2007), it is expected that eddy-present and eddy-rich models will differ in their decadal variability and sensitivity to changes in wind stress of gyres from eddy-parameterized models (*medium confidence*). Nonetheless, important aspects of gyre strength depend primarily on forcing and not resolution, allowing long term changes in gyre strength to be investigated with low resolution climate models (Hughes and de Cuevas, 2001; Yeager, 2015).

Under future scenarios RCP4.5 and RCP8.5, the AR5 (Collins et al., 2013) assessed an intensification and poleward extension of the southern Hemisphere subtropical gyres in the 21st century. New evidence since the AR5 further reinforce their conclusions which are now extended to all subtropical gyre systems, in both the northern and southern hemispheres (Yang et al., 2016a, 2020). CMIP6 models project changes in WBCs that

ACCEPTED VERSION SUBJECT TO FINAL EDITING

are consistent with projected changes in the surface winds. Under strong radiative forcing, in scenario SSP5-8.5, CMIP6 models project that the East Australian Current Extension and Agulhas Current Extension will intensify in the 21st century, while the Gulf Stream and Brazil Current will weaken (Figure 9.11). Although CMIP5/CMIP6 are limited in resolution, *medium confidence* is given to changes in western boundary currents due to consistency across generations of climate models, including CMIP6, despite changes in model structure, resolution and parameterisations.

[START FIGURE 9.11 HERE]

Figure 9.11: Simulated barotropic streamfunction, surface speed and major current transport in CMIP5 and CMIP6. (a) Mean barotropic streamfunction (Sv) 1995-2014 and projected barotropic streamfunction change (Sv, 2018-2100 vs. 1995-2014) under (b) SSP5-8.5. (d) Mean surface (0-100 m) speed (m/s) and projected surface speed change (m/s, 2081-2100) versus 1995-2014 under (e) SSP5-8.5. (c, f) Median and likely range of 1995-2014 and 2081-2100 transport of 3 currents with the largest transport change and 4 with the largest fractional change (Sen Gupta et al., 2016). (c) Deep currents: Agulhas Extension (ACx), Gulf Stream (GS), Gulf Stream Extension (GSx), Tasman Leakage (TASL), East Australia Current Extension (EACx), Indonesian Throughflow (ITF), and Brazil Current (BC). (f) Shallow currents: as for deep but with New Guinea Current (NGC), and without ACx. No overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.11 HERE]

The SROCC (Collins et al., 2019) concluded with *high confidence* that ITF transport from the Pacific to Indian ocean has increased in the past two decades, as a result (*medium confidence*) of an unprecedented intensification of the equatorial Pacific trade wind system. Section 2.3.3.4 assesses that there is *high confidence* that the increase in the ITF over the past two decades is linked to multi-decadal scale variability rather than a longer-term trend. Consistently, in the future, as winds change under increased radiative forcing, most models project a decline of the ITF on the centennial timescale (Figure 9.11). Indeed, one of the clearest changes of ocean current transport simulated by climate models is a weakening of the Indonesian Throughflow projected in CMIP5 simulations under RCP4.5 and RCP8.5 scenarios (Sen Gupta et al., 2016; Stellema et al., 2019), as well as in CMIP6 simulations under the SSP5-8.5 scenario (*high confidence*, Figure 9.11).

The SROCC reports with *high confidence* that the Agulhas leakage from the Indian to the Atlantic ocean has increased in the past two decades (Collins et al., 2019), and there is no additional evidence since then allowing to revisit this assessment (Biastoch et al., 2015; Loveday et al., 2015; Lübbecke et al., 2015). There is *low confidence* in future projections of Agulhas leakage because most CMIP models cannot directly simulate it, due to coarse resolution. However, there is *medium evidence* that the strength of the Southern Hemisphere westerlies controls Agulhas leakage (Durgadoo et al., 2013; Biastoch et al., 2015; Loveday et al., 2015), and *high confidence* that the strength of the Southern Hemisphere westerlies will increase under increased radiative forcing except in lower warming scenarios (SSP1-1.9, SSP1.2-6; Section 4.3.3.1) (Bracegirdle et al., 2020). There is also evidence that increasing Agulhas leakage is consistent with observed change of the temperature and salinity structure in the Atlantic ocean, and with variability of the AMOC (Section 9.2.3.1) (Biastoch et al., 2015). This range of indirect evidence provides *medium confidence* that the Agulhas leakage will increase in the 21st century, except for the strongest mitigation scenario (Figure 9.11).

The SROCC assessed that the annual Bering Strait volume transport from the Pacific to the Arctic Ocean increased from 2001–2014, consistent with an estimated increased northward heat transport of about 60% from 2001–2014, and an increased freshwater transport of 30±20 $km^3\ yr^{-1}$ from 1991 to 2015 (Meredith et al., 2019). Section 2.3.3.4 assesses that volume transport from the Pacific to the Arctic has increased since the 1990s from 0.8 Sv to 1.0 Sv over 1990-2015. Realistic representation of the Bering Strait transport in the current generation of climate models is challenging because the strait is narrow compared to the resolution of climate models

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Clement Kinney et al., 2014; Aksenov et al., 2016). For the Atlantic to Arctic transport, Section 2.3.3.4 reports that the major branches of Atlantic Water inflow across the Greenland-Scotland Ridge have remained stable, with only the smaller pathway of Atlantic Water north of Iceland showing a strengthening trend during 1993-2018. Section 2.3.3.4 also assesses that the Arctic outflow remained stable from the mid 1990s to the mid 2010s. Future changes in these currents have not yet been studied in CMIP6 models.

9.2.3.5 Eastern Boundary Upwelling Systems

Eastern boundary upwelling systems (EBUS) exist where trade winds draw cold and generally low-pH/low-oxygen waters upward. Coastal upwelling plays a key role in supplying the food chain with nutrients, hence the richness and productivity of EBUS (Bindoff et al., 2019). The SROCC (Bindoff et al., 2019) assessed with *high confidence* that three out of the four major EBUS have experienced large-scale wind intensification in the past 60 years (only the trend for the Canary current is considered uncertain). However, it also emphasized that various processes can also modulate or even reverse wind trends locally (Bindoff et al., 2019). Here we revisit the SROCC (Bindoff et al., 2019) assessment based on evidence showing *low agreement* between studies that have investigated trends over past decadess of upwelling-favourable winds (Varela et al., 2015). This *low agreement* has been related to differences in wind products, season of interest, and length of the considered time series (Varela et al., 2015). Based on this, we assess that only the California current system has experienced large-scale upwelling-favorable wind intensification over the period 1982-2010 albeit with regional differences (García-Reyes and Largier, 2010; Seo et al., 2012). In the Benguela, Canary, and Humboldt systems, large-scale, upwelling-favourable wind trends are ambiguous, owing to *low confidence* in long-term in situ marine wind data (Cardone et al., 1990; Bakun et al., 2010) and *low agreement* among available studies (Narayan et al., 2010; Sydeman et al., 2014; Varela et al., 2015). Our assessment confirms the SROCC (Bindoff et al., 2019) in that high natural variability of EBUS and their inadequate representation by most climate models gives *low confidence* in attribution of observed changes, while anthropogenic changes are projected to emerge primarily in the second half of the 21st century (*limited evidence*: one model and one study) (Brady et al., 2017).

Under increased radiative forcing, the SROCC (Bindoff et al., 2019) assessed that climate models project, in the 21st century, a reduction of wind and upwelling intensity in EBUS at low latitudes and enhancement at high latitudes under scenario RCP8.5, with an overall reduction in either upwelling intensity or extension. It also highlighted that coastal warming and wind intensification may lead to variable countervailing responses to upwelling intensification at local scales. Despite differences among EBUS (Wang et al., 2015a), there is growing evidence since the SROCC in this pattern of change. While it has long been hypothesized that for upwelling winds, change is linked to air temperature contrast between ocean and land (Bakun, 1990), this hypothesis has increasingly been challenged. Changes in sea level pressure and wind fields in EBUS appear to be primarily tied to those affecting subtropical highs (García-Reyes et al., 2013). Poleward expansion of the Hadley cell (Section 2.3.1.4.1) (Staten et al., 2018) and the related poleward migration of subtropical highs (He et al., 2017; Cherchi et al., 2018), produce robust patterns of changes of reduced upwelling at low latitude and enhanced upwelling at high latitude (Echevin et al., 2012; Belmadani et al., 2014; Bettencourt et al., 2015; Rykaczewski et al., 2015; Sousa et al., 2017; Lamont et al., 2018; Sylla et al., 2019). These patterns are most apparent in summer in both hemispheres. Synoptic variability of upwelling winds, important to the functioning of upwelling ecosystems (García-Reyes et al., 2014), may also be affected by climate change (Aguirre et al., 2019). However, coarse resolution model projections of winds in upwelling regions may be more consistent than higher-resolution projections as these regions are highly sensitive to resolution (Small et al., 2015).

Projected future annual cumulative upwelling wind changes at most locations and seasons remain within ±10-20% of present-day values in the 21st century, even in the context of high-end emission scenarios (4xCO2 or RCP8.5) (*medium confidence*). Changes due to wind stress curl and alongshore pressure gradients do tend to agree with alongshore wind changes (Oerder et al., 2015a; Sylla et al., 2019). Direct estimation of oceanic upward transport (Oyarzún and Brierley, 2019; Sylla et al., 2019) and nutrient flux into the euphotic layer (Jacox et al., 2018) provide a meaningful estimator of upwelling, integrating all relevant processes, including changes in wind stress curl. However, there is *limited evidence* from vertical velocity of climate

ACCEPTED VERSION SUBJECT TO FINAL EDITING

models and missing processes in coarse-resolution climate models that presently limit this approach. Change in upper ocean stratification (Section 9.2.1.3) is projected to increase confinement of upwelling vertical velocities to near the ocean surface (Oerder et al., 2015a; Oyarzún and Brierley, 2019) (*high confidence*).

In summary, the SROCC and we conclude that the California current system has experienced some upwelling-favourable wind intensification since the 1980s (*high confidence*), while *low agreement* among reported wind changes in the Benguela, Canary, and Humboldt systems prevents a similar assessment. As in the SROCC, there is *low confidence* in attribution of observed changes to anthropogenic or natural causes. New evidence reinforces our confidence in the SROCC assessment that under increased radiative forcing, EBUS winds will change with a dipole spatial pattern within each EBUS of reduction (weaker and/or shorter) at low latitude, and enhancement (stronger and/or longer) at high latitude (*high confidence*). There is *medium confidence* that, across all scenarios, upwelling wind changes in EBUS will remain moderate in the 21st century, within ±10-20% from present-day values.

9.2.3.6 Coastal Systems and Marginal Seas

Beyond the world's coastlines lie the shoreline, shallow estuaries, continental shelves, and deeper fjords and slopes, where depths increase rapidly from the shelves to the deep ocean floor. It is more difficult to transport fluid across the shelf-break or slope than along (Brink, 2016), and estuaries and shelves have complex circulations and mixing leading to indirect connections between the inner shelves and coastlines and offshore conditions. Coastal processes link to both large-scale metrics of climate and regional effects, from changing rivers and estuaries, melt and runoff to deep water, to how changes offshore affect regional and coastal conditions.

Shelf-deep ocean exchanges involve eddying, tidal, or turbulent motions and small-scale topography such as submarine canyons; high resolution observations and models are needed to capture these effects (Greenberg et al., 2007; Capet et al., 2008; Allen and Durrieu de Madron, 2009; Colas et al., 2012; Trotta et al., 2017). Example coastal processes that introduce uncertainty into large-scale projections are exchange of CDW across the Antarctic shelf-break, which affects AABW formation and Antarctic ice shelf-ocean interaction (Sections 9.2.2.3, 9.2.3.2) (Stewart and Thompson, 2013, 2015), river and estuarine plumes and their responses to water level and hydrology change (Banas et al., 2009; Sun et al., 2017), fjord dynamics linked to glacial outflows (Straneo and Cenedese, 2015; Torsvik et al., 2019), and changing formation of water masses in marginal seas (Kim et al., 2001; Greene and Pershing, 2007; Giorgi and Lionello, 2008; Renner et al., 2009). Downscaling projections to the local level allows process detail (Foreman et al., 2013; Mathis and Pohlmann, 2014; Meier, 2015; Tinker et al., 2016). Some processes can only be simulated when coastal models are forced by larger-scale models of the atmosphere, cryosphere, or hydrosphere (Seo et al., 2007, 2008; Somot et al., 2008; Oerder et al., 2015b; Renault et al., 2016; Zhang et al., 2016a; Wåhlin et al., 2020), including the addition of tides (Janeković and Powell, 2012; Timko et al., 2013; Tinker et al., 2015; Pickering et al., 2017; Hausmann et al., 2020). Due to coastal process complexity and small scale, linking the effects of coastal ocean changes to global ocean changes requires high resolution modelling (Holt et al., 2017, 2018), two-way nesting, or local mesh refinement (Fringer et al., 2006; Zhang and Baptista, 2008; Mason et al., 2010; Dietrich et al., 2012; Hellmer et al., 2012; Ringler et al., 2013; Wang et al., 2014b; Zängl et al., 2015; Zhang et al., 2016b; Soto-Navarro et al., 2020). Coarse climate models and even HighResMIP models do not represent some coastal phenomena such as cross-shelf exchanges and sub-mesoscale eddies which require 1km or finer resolution. Thus, there is *low confidence* in projecting centennial scale coastal climate change where regional downscaling or refinement is lacking. There is *high confidence* in the ability of regional coupled models to improve coastal climate change process understanding and provide regional information (Section 12.4), but many sites globally await such projections.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

9.2.4 Steric and dynamic sea-level change

9.2.4.1 Global mean thermosteric sea-level change

Changes in globally averaged ocean heat content (OHC) cause global mean thermosteric sea-level (GMTSL) change (Box 9.1). The observed increased OHC for 1971-2018 of 325 to 546 ZJ (*very likely* range, Section 7.2, Box 7.2) has led to a GMTSL rise of 0.03 to 0.06 m out of a total GMSL of 0.07 to 0.15 m (*very likely* range, Section 2.3.3.3, Table 2.7, Table 9.5, Cross-Chapter Box 9.1).

Projections of GMTSL rise in the AR5 (Church et al., 2013a) and the SROCC (Oppenheimer et al., 2019) were derived from the CMIP5 ensemble, after removing drift estimated based on pre-industrial control simulations. Differences between removing a linear and a quadratic drift are small (Hermans et al. 2021) (Hobbs et al., 2016b; Hermans et al., 2021). These prior assessments filled in projections for models that did not provide GMTSL rise for all scenarios, by calculating the heat content of the climate system from global surface air temperature and net radiative flux, then converting this to GMTSL rise using each model's diagnosed expansion efficiency coefficient. In the AR5, the associated uncertainties were derived by assuming a normal distribution, with the 5^{th}-95^{th} percentile CMIP5 ensemble range taken as the *likely* range (±1 standard deviation).

In this report, global surface air temperature projections are not derived directly from the CMIP6 ensemble (Box 4.1). Therefore, in order to produce projections of OHC and GMTSL rise that are consistent with the report's assessment of equilibrium climate sensitivity and transient climate response (Section 7.5.2.2), this chapter employs a two-layer energy budget emulator (Supplementary Materials 7.SM.2, 9.SM.4.3). Since the AR5, climate model emulators have been increasingly used to predict GMTSL (Kostov et al., 2014; Palmer et al., 2018, 2020; Nauels et al., 2019) (Cross-Chapter Box 7.1). The expansion efficiency coefficient that relates GMTSL and OHC for the two-layer emulator has a mean and standard deviation of 0.113 ± 0.013 m/YJ (Supplementary Material 9.SM.4.3). This approach yields a *likely* thermosteric contribution between 1995 to 2014 and 2100 that represents a minimal change from the AR5 and the SROCC (Table 9.8). The two-layer emulator GMTSL projected median and 17^{th}-83^{rd} percentile, or *likely*, range is 0.12 (0.09-0.15) m for SSP1-1.9, 0.14 (0.11-0.18) m for SSP1-2.6, 0.20 (0.16-0.24) m for SSP2-4.5, 0.25 (0.21-0.30) m for SSP3-7.0, and 0.30 (0.24-0.36) m for SSP5-8.5 by 2100 (Section 9.6.3.2; Tables 9.1, 9.8,9.9). The two-layer model heat content increases slightly faster than that of the total depth CMIP6 ensemble, which is related to its role in the assessed energy balance (Section 7.SM.2), but with a similar ensemble spread (Table 9.1). Projecting the *likely* factor by which 1995-2014 to 2081-2100 ocean heat content change exceeds change over 1971 to 2018 in CMIP6 yields 3 to 5 for SSP1-2.6, 4 to 6 for SSP2-4.5, 5 to 7 for SSP3-7.0, and 5 to 8 for SSP5-8.5. The two-layer model *likely* equivalents are 2 to 3 for SSP1-2.6, 3 to 4 for SSP2-4.5, 4 to 5 for SSP3-7.0, and 4 to 6 for SSP5-8.5.

For reconstructions, the expansion efficiency coefficient is required for the conversion between ocean temperature and steric sea level over a specific time scale. Combining the assessed sea level and energy data over 1995 to 2014 (drawn from the analysis in Cross-Chapter Box 9.1) results in a coefficient of 0.1210 ± 0.0014 m/YJ, or 0.6607 ± 0.0076 m/ºC in terms of mean ocean temperature. The two-layer emulator assessment used in AR6 results in 0.113 ± 0.013 m/YJ, or 0.617 ± 0.071 m/ºC (Appendices 7.SM.2, 9.SM.4). Both of these estimates are in line with an independent estimate of 0.70 m/ºC (Hieronymus, 2019) and other estimates, e.g., 0.116 ± 0.011 m/YJ (Kuhlbrodt and Gregory, 2012), but are significantly larger than the temperature to sea level conversion used in the AR5 (0.42 m/ºC based on SST and the estimated range from (Levermann et al., 2013)). The expansion coefficient is not fixed across models nor in time, as it varies depending on which water masses are storing the added heat and the commitment time scale (Hallberg et al., 2013). For paleoclimate, a scaling for sea surface temperature (0.6 m/ºC) or GSAT (see Cross-Chapter Box 2.3) can be estimated, but mean ocean temperature is in phase with steric sea-level change while sea surface temperatures are not (Shakun et al., 2012; Tierney et al., 2020) (Figure 9.9). Thus, while conversions between OHC, mean ocean temperature and GMTSL across applications are within uncertainty ranges (*medium confidence*, Table 9.1), little consistency is found when correlating these variables to SST or GSAT which may vary independently.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Short-lived climate forcers (Sections 6.3, 6.6.3) are associated with a sea-level commitment, due to an ocean heat content and mean ocean temperature response that lasts substantially longer than their atmospheric forcing and SST response, although not as long as the sea-level commitment associated with CO_2 emissions (Sections 9.2.1.1, 4.4.4). For example, Zickfeld et al., (2017) find that about 70% of the thermosteric sea-level rise associated with methane forcing would persist 100 years after the elimination of methane emissions and 40% would persist for over 500 years.

In summary, consistent relationships between OHC (Section 9.2.2.1), mean ocean temperature and GMTSL are found using two-layer emulators, CMIP6 models, and modern and paleo observations to provide *medium confidence* in the 0.113 ± 0.013 m/YJ, or 0.617 ± 0.071 m/ºC *likely* ranges of assessed conversion values. It is possible to estimate relationships between SST or GSAT change and GMTSL rise, but conversions are not generally applicable and depend on time scale and application.

[START TABLE 9.1 HERE]

Table 9.1: Projected contributions to median and 17-83% (parentheses) and 5-95% (square brackets) ranges of thermosteric sea level from AR5 (Church et al., 2013), CMIP6 (Jevrejeva et al., 2020; Hermans et al., 2021) and the two-layer energy balance model (described in Sections 7.SM.2, 9.SM.4 and Box 4.1) averaged over 2081-2100, with respect to a baseline of 1995-2014. Note that AR5 and SROCC interpret 5-95% range as the *likely* range, while in this table square brackets are used for consistency.

Study	RCP2.6/SSP1-2.6	RCP4.5/SSP2-4.5	RCP8.5/SSP5-8.5

9.2.4.2 Ocean dynamic sea-level change

Projections of ocean dynamic sea-level change (Box 9.1) on multiannual timescales resemble the patterns of steric sea-level change in the open ocean (Figures 9.11 and 9.12) (Lowe and Gregory, 2006; Pardaens et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2011; Couldrey et al., 2020). On shorter timescales, especially in extratropical coastal areas, there may be an important barotropic component (also called bottom pressure change) due mostly to changes in wind-driven circulation and eddies apparent in the variance of ocean dynamic sea level (Figure 9.12, (Roberts et al., 2016; Hughes et al., 2018). This component is highly sensitive to ocean model resolution (Chassignet et al., 2020). Steric sea-level change is associated with local changes in temperature and salinity, which come about through changes in surface fluxes of heat and freshwater (Section 9.2.1.2) and through redistribution of existing water masses by changed ocean circulation and mixing processes (Figure 9.12**,** Sections 9.2.2.1, 9.2.3). Redistribution of water masses often involves anticorrelated thermosteric and halosteric changes (Figure 9.12), especially in the Atlantic (Pardaens et al., 2011; Bouttes et al., 2014; Durack et al., 2014; Griffies et al., 2014; Han et al., 2017).

[START FIGURE 9.12 HERE]

Figure 9.12: (a-f) CMIP6 multi-model mean projected change contributions to relative sea level change in (a,d) steric sea level anomaly, (b, e) thermosteric sea level anomaly, and (c, f) halosteric sea level anomaly between 1995-2014 and 2081-2100 using a method that does not require a reference level (Landerer et al., 2007). Global mean change has been removed from these figures, consistent with the methods in Sections 9.6.3 and 9.SM.4.3 and the definitions of (Gregory et al., 2019). See Figure 9.27 for GMSL. (g-i) Standard deviation of ocean dynamic sea-level change from (g) Aviso observations (10 day highpass filter), (h) 5-day mean of high-resolution OMIP-2 models forced with observed fluxes, and (i) 5-day mean of low-resolution OMIP-2 models which are comparable in resolution to the models in (a-f). No overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.12 HERE]

Ocean dynamic sea-level change is strongly affected by internal variability (Section 9.6.1.4), partly from interannual to decadal coupled atmosphere-ocean modes of variability via wind-driven redistribution (Annex IV; Griffies et al., 2014; Han et al., 2017) and partly from intrinsic ocean variability, particularly in higher resolution simulations (such as HighResMIP), which statistically resemble observations, even on short timescales (Figure 9.12, Griffies et al., 2014; Sérazin et al., 2016; Llovel et al., 2018; Chassignet et al., 2020). High-resolution simulations are not used in relative sea level projections (Section 9.6.3) due to the limited range of forcing scenarios. The most marked feature of long-term regional sea-level change in the continuous satellite altimetry record, beginning in 1992, is the east-west dipole in the Pacific Ocean (rising more rapidly in the east, see also Section 9.6.1.3), which persisted until 2015 and can be explained by anomalously strong trade winds (Merrifield et al., 2012; England et al., 2014; Griffies et al., 2014; Takahashi and Watanabe, 2016; Han et al., 2017) together with associated changes in surface heat flux (Piecuch et al., 2019). The most notable features of sub-annual variability in altimetry are eddies and tides, which are directly simulated only in high resolution models (Haigh et al., 2019; Chassignet et al., 2020).

Projections of the pattern and amplitude of regional ocean dynamic sea-level change in CMIP6 and previous model generations show a large model spread, of a similar size to the geographical spread (Figure 9.12). The model spread derives from model dependence of changes both in surface fluxes (Section 9.2.1.2) and in the ocean response (Section 9.2.2). The spread is similar in CMIP6 and CMIP5, and is largest in regions with large projected variations in ensemble-mean ocean dynamic sea-level change (Lyu et al., 2020a), such as the Southern Ocean dipole with an ocean dynamic sea-level rise north of the ACC and a fall to the south, the Atlantic dipole with a sea-level rise north of 40ºN and a fall in 20-40ºN, the north-west Pacific dipole, and the large sea-level rise in the Arctic (Church et al., 2013a; Slangen et al., 2014b; Bilbao et al., 2015; Slangen et al., 2015; Gregory et al., 2016; Chen et al., 2019a; Couldrey et al., 2020; Lyu et al., 2020a). Patterns of change are consistent between model simulations and observations (*medium confidence*). The major model ensemble-mean features resemble thermosteric sea level change, as expected from altered input of heat to the ocean without changing circulation, while model spread results from the diversity in redistribution of the heat content of the unperturbed ocean (Section 9.2.2.1; (Bouttes and Gregory, 2014; Gregory et al., 2016;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Huber and Zanna, 2017; Couldrey et al., 2020; Lyu et al., 2020b; Todd et al., 2020)).

The Southern Ocean meridional dipole is driven by a northward advection of excess heat (from changes in surface fluxes) by the wind-driven circulation followed by subduction or diffusive uptake in mid-latitudes, northward redistribution of existing heat by the strengthening of that circulation, and the meridional contrast in thermal expansivity due to its temperature-dependence (Armour et al., 2016; Gregory et al., 2016; Couldrey et al., 2020; Lyu et al., 2020b; Todd et al., 2020).
